Sodium Chloride Intake and Work During Dry Heat.

—Taylor and his associates deal with the effects of work in heat on cardiovascular and related functions. The effects of three levels of sodium chloride intake on cardiovascular functions were studied in 49 "normal" men at work and at rest during exposure to hot dry conditions. Men maintained on 6 Gm. of sodium chloride daily (low intake) had higher pulse rates and rectal temperatures than men receiving 15 Gm. daily (moderate intake). The deleterious effect of the low salt intake was also reflected in poorer postural cardiovascular adjustment. The men on the low salt intake lost more than twice as much body weight, drank less water and sweated less than the men on the moderate salt intake. The low salt intake resulted in an average net deficit of 13 Gm. of sodium chloride for three days in the heat. The men on the moderate salt intake appeared to be in sodium chloride balance after three days in the heat. Heat exhaustion and prostration, characterized by nausea, vomiting, tachycardia, hypotension, vertigo, dehydration and collapse, occurred in 25 per cent of the men on the low salt intake and in only 2.5 per cent of the men on the moderate salt intake. Although pronounced hypochloremia was observed in many instances, heat cramps did not occur. There was little or no relation between the concentration of chloride in the sweat and the rectal temperature. It is concluded that heat exhaustion and ability to work in the heat are almost wholly dependent on cardiovascular function and that a moderate salt intake is more important to preserve this function than to prevent heat cramps. Hypochloremia is not the only factor in heat cramps. The

sodium chloride requirement of unacclimatized men who are sweating 5 to 8 liters a day is not greater than 13 to 17 Gm. daily. An increase in salt intake above this level results in increased loss of salt and water in the urine with no apparent advantage.

Sulfonamides in Chronic Osteomyelitis.—In 1941 Dickson, Diveley and Kiene reported a series of 22 cases of chronic osteomyelitis in which the infected soft tissue and bone had been carefully excised, the wound dusted with sulfathiazole powder and closed in layers, and the extremity immobilized in a plaster cast. The patients were given sulfathiazole by mouth for five days before the operation and for about fifteen days after the operation. Healing by primary intention occurred in 82 per cent of the patients. Key used this method in operating on 101 consecutive patients with chronic pyogenic infection of bone. Including 11 amputations, 60 of the wounds healed by primary intention, but sinuses later developed in 4. The percentage of primary healing in this series was less than that obtained by Dickson, Diveley and Kiene. However, their series

apparently represented a selected group of cases in which it was possible to perform a satisfactory excision of the focus and close the wound. The author's series represented every case of chronic bone infection in which he had operated in the past two and one-half years. Key believes that the method is superior to Orr's method. The closed method with chemotherapy is not dangerous and enables the surgeon to swing flaps, cover bones and eliminate large areas of scarring in a manner which is not possible by any other method.

Neuromuscular Disorders in Poliomyelitis.—Moldaver carried out a series of investigations to test the Kenny concept of poliomyelitis. Neuromuscular degeneration, such as would be caused by lesions of the anterior horn cells, was explored by the chronaxia method; the so-called spasm was studied in some patients, mostly by electromyograms. Fifty-one patients were tested. The time elapsed between the onset of the disease and the tests varied from ten days to one year. Muscles called "alienated" as well as muscles in "spasm" were explored, muscles considered to be normal clinically also were tested. It was always found that the more advanced the degeneration, the less extensive was the "spasm." The author emphasizes that "spasm" is not the most damaging symptom of the disease, it is a complex and ill defined phenomenon under which several different conditions are included. "Spasm" does not lead to neuromuscular degeneration. In paralytic and paretic muscles called "alienated" there was always some degree of neuromuscular degeneration. Among these muscles some were partially denervated; these have a good chance to recover. Some others were totally denervated and therefore will not recover. There is no clinical evidence of "incoordination" in the ordinary sense. The patient attempts voluntarily or involuntarily to use a stronger muscle for a weak or paralyzed one. This abnormal use of an extremity is substitution and not "incoordination."

Survival of Bacteria on Communion Cup.—The opinion appears to be generally held that the use of the silver chalice as a common communion cup is highly undesirable from the hygienic point of view. Burrows and Hemmens present evidence which indicates that bacteria swabbed on the polished surface of the silver chalice die off rapidly. Experiments on the transmission of test organisms from one person to another

by common use of the chalice showed that approximately 0.001 per cent of the organisms are transferred even under the most favorable conditions, when conditions approximated those of actual use, no transmission could be detected. Only small numbers of bacteria from the normal mouth could be recovered from the chalice immediately after its use by 4 persons. It is concluded that the silver communion cup is not an important vector of infectious disease.

Implantations of Toxic Goiter in Spondylarthritis Ankylopoietica.—According to Mandl, spondylarthritis ankylopoietica is found chiefly in males. It is characterized by rapidly spreading ossification of the small ligaments of the spinal column to the areas above and below those first attacked. At a later stage the hip joint becomes involved, and there is a union between the fifth lumbar vertebra and the sacroiliac joint. The spine becomes increasingly stiff, and there is local as well as radiating pain. It may be difficult to differentiate between spondylarthritis ankylopoietica and certain types of atrophic or hypertrophic spondylarthritis. Various treatments have been tried. The antirheumatics and exercise treatment give little relief. Roentgen treatment may lessen pain, but the author doubts that it accomplishes remissions. The endocrine approach led to parathyroidectomy to lower the calcium level of the blood. Apart from the fact that increased blood calcium is only rarely encountered in spondylarthritis ankylopoietica, a number of authors who tried it eventually abandoned the method since it produced no satisfactory results. According to Crotti implantations of thyroid gland have been tried repeatedly. Mandl used implants of thyrotoxic goiter for 4 patients with spondylarthritis ankylopoietica. The tissue was taken from patients of the same blood group and was implanted into the posterior rectus sheath of the spondylarthritic patient. Three of the patients had typical spondylarthritis ankylopoietica. In 2 the toxic goiter implants produced considerable improvement while in the third decalcification of the skeleton was noted after eight months. In 2 less severe cases internal endocrine therapy with thyroidin was given, and both improved for the duration of the treatment. This method is merely considered a symptomatic measure. There is no indication of a relationship between spondylarthritis ankylopoietica and thyroid function. The effect probably occurs concurrently with an increased basal metabolic rate.

Diabetes Mellitus and Pregnancy.—Laviates and his collaborators studied 31 pregnancies in 23 diabetic women delivered in the New Haven Hospital between 1921 and 1943. Eight of the 14 primigravidae were 27 years of age or more, four of the 9 multigravidae were 39 years or older. Hypertrophy of the fetal pancreas and lactation probably have no considerable effect on the tolerance for carbohydrate. Tolerance for carbohydrate falls quite regularly during pregnancy, the most striking fall usually beginning at six to eight months, with return to the original level at or shortly before term. Obvious hydramnios occurred five times. There was no maternal mortality. Glycemia occurred in 10 patients. Of these, 4 with hypertensive toxemia had had severe hypertension before the onset of pregnancy. Five of the 6 patients with preeclamptic toxemia were 28 years or older. Three of the 6, including the young one, had labile hypertension prior to the pregnancy. Of the 8 patients with 2 pregnancies each, 2 had toxemia both times, 6 neither time. The risk of toxemia is slight in young patients without previous vascular disease and in multigravidae without previous hypertension or toxemia. The babies tend to be large. Nine of the 23 mothers lost babies. Twelve of the 31 babies were lost. There was no correlation between fetal mortality and maternal toxemia. The authors feel that diabetes is not an indication for abdominal delivery. Patients who have a past history of repeated fetal accidents must be given a guarded prognosis, and if there are living children pregnancy should be discouraged. Patients with hypertension before pregnancy or with previous toxemia of pregnancy should be considered in the same category, without consideration of the diabetes.

Reactions to Transfusions of Banked Blood.—Carlson analyzes the record of a hospital blood bank. During a two year period 3,388 transfusions of banked blood were given. Reactions occurred in 6 per cent of the transfusions. Of these reactions 11, or 0.32 per cent, of the total number of transfusions given were serious. These included 3 hemolytic reactions, 3 cases of jaundice without other evidence of hemolytic reaction, 2 anaphylactic reactions and 3 cases in which cardiovascular embarrassment was caused by a transfusion. There was 1 death as a result of transfusion. The hemolytic reaction is the most serious of the transfusion reactions. In contrast to the view that intergroup incompatibility is the cause of all hemolytic reactions, other investigators feel that these reactions may be caused by irregular isoagglutinins present in bloods of the same type. Probably the most important isoagglutinin is that directed against the Rh factor. It has been shown that Rh-positive blood administered to a previously sensitized Rh-negative recipient will cause a severe, frequently fatal, hemolytic reaction. The incompatibility of the cells and serums of the donor and recipient is not evident when the conventional cross-matching technic is used. During the period considered in this study, determinations of presence of the Rh factor were not a routine procedure, so it is not known whether this type of incompatibility was responsible for any of the hemolytic reactions encountered.

Clinical Study of Influenza B.—Stansfeld and Stuart-Harris compared a group of 24 cases of influenza B which were proved by serologic tests with a group of 12 clinically similar cases occurring in the same outbreak but showing no rise in antibody to either A or B virus (classified as influenza Y) and also with a collected series of 60 cases of influenza A. Little difference was apparent among the three groups. The clinical findings were in general agreement with those of patients admitted to an American army hospital, whose chest roentgenograms, leukocyte counts and differential counts were not diagnostically significant. Influenza A and influenza B appear to be clinically indistinguishable in the individual patient.

Influenza in Britain in 1942 and 1943.—Stuart-Harris and his associates direct attention to the changing character of recent influenza epidemics. As a four year cycle had prevailed in England since 1929, it was anticipated that 1941 might be a peak period; nevertheless the outbreaks that winter were relatively mild. Laboratory studies indicated that much of the sporadic clinical influenza during January 1941 was due to influenza A virus, but ferrets were less readily infected than in earlier outbreaks. During the winter and spring of 1941-42 and 1942-43 a study of influenza has been continued. During the winter of 1942-43 an investigation of acute respiratory infections was carried out in two divisions. In division B the cases were subdivided into febrile and afebrile, but in division A they included all cases of colds, sore throats, pharyngitis, tonsillitis, influenza, bronchitis and pneumonia, whether febrile or not. Early in 1942 examination of convalescent serums by the Hirst technic and transmission of garglings to ferrets and developing eggs failed to reveal evidence that the mild influenza outbreaks then occurring were due to influenza viruses A or B. A mild increase in the incidence of acute respiratory infections early in 1943 was associated with serologic evidence of influenza B virus infection. Later in the season (March to June) small scattered outbreaks of A virus infection were encountered. The Hirst technic is exceedingly valuable in detecting virus B outbreaks, provided the factors causing variation in the inhibition titers of any particular serum are recognized and suitable precautions are taken against false readings. Like Taylor and his associates, the authors have found it useful to instil garglings into ferrets and examine the serum by the Hirst technic for antibody rise. In a proportion of cases in which the convalescent serum of the human patient showed a significant rise against virus B the ferret serum was also positive.

Primary Pulmonary Tuberculosis.—According to Murray, primary tuberculous infection develops in those who previously have not been sensitive to tuberculin, secondary infection in those who are already sensitive to tuberculin. Primary infection may appear in any part of the lung; secondary infection usually starts in the upper third of the lung. The tracheo-

bronchial lymph nodes become infected and enlarged in primary infection, whereas the draining lymph nodes seldom become involved in secondary infection. The caseous area in primary infection usually becomes encapsulated and calcified; in secondary infection caseous areas usually proceed to liquefaction and cavitation. Hematogenous dissemination, not clinically evident at the time, takes place in most cases of primary infection; in secondary infection the lesion tends to spread by infiltration and by the bronchi. The primary focus in the lung may become completely healed in the course of time, biologically as well as anatomically, leaving behind a small scar or a calcified nodule. Though encapsulation and calcification also occur in the neighboring lymph nodes there usually remains some caseous material within the capsule, and here live bacilli may persist indefinitely. Emphasis is laid on the importance of gastric lavage followed by culture or guinea pig inoculation as the most effective method of proving the cause. Except when constantly exposed to heavy dosage or under abnormal conditions, the symptoms are mild and death during the primary infection phase is comparatively rare. The most important procedure in the treatment of primary tuberculosis is to separate the patient from the source of infection and thus to protect him from continuous dosage with bacilli. Rest is the next most important item. Six to eight weeks' rest is likely to give sufficient time for the lesions to become encapsulated. Most patients recover undiagnosed and untreated. Sanatorium care is not advisable on account of the short duration of illness and the danger of continued exogenous infection to the patient. Ten cases of primary pulmonary tuberculosis were diagnosed in the adult wards of the author's hospital during the last year. Three of the patients were under 20 years of age; the other seven were between 20 and 28. With the exception of 2 patients who developed a pleural effusion, the symptoms were mild and of short duration.

Zentralblatt für Chirurgie, Leipzig

Influence of Weather and Solar Activity on Fatal Pulmonary Embolism.—The Reimann-Hunzikers investigated the influence of weather and of solar activity on the mortality from embolism on the basis of 224 fatal pulmonary embolisms that were subjected to necropsy in Basel. Embolism occurs rarely on days of the passage of cold fronts. However, there is a high incidence of embolism on days with storm fronts and heat thunder storms. During winter there is a high frequency of embolism during occlusions. A foehn increases the mortality from embolism. During winter embolism is rare in the presence of continental air bodies, but in the presence of maritime and polar-maritime air bodies embolisms are frequent. During summer mortality from embolism increases during the passage of tropical maritime, tropical continental and polar maritime air. Change of an air body to maritime air increases the incidence of embolism during winter but not during summer. In winter of embolism is rare in the presence of continental air. Investigating the influence of solar activity, the authors found that on days with a high incidence of embolism the average magnetic disturbance of the ionosphere is greater than on other days. They also observed an indication of a possible relationship in periodicity between mortality from embolism and solar rotation. There was an increase in cases of eclampsia at times of increased mortality from embolism. It was also observed that, at the time of the culmination of foci of activity in the central meridian of the sun, embolisms increased. There was an increase in embolism mortality on the days following the new appearance of sun spots.

Book Notices

Elements of Medical Mycology. By Jacob Hyams Swartz, M.D., Assistant Professor of Dermatology, Harvard Medical School and Postgraduate School, Boston. Introduction by Fred D. Weldman, M.D., Professor of Dermatological Research, University of Pennsylvania, Philadelphia. Cloth. Price, \$4.50. Pp. 179, with 78 illustrations. New York: Grune & Stratton, 1943.

Until a relatively short time ago there was lack of a textbook on mycology in English. This has been relieved by the appearance of several American works, which means at least two things. Physicians want and need to know more about fungi, and there are enough earnest students of mycology to write about it. A large part of the publications that are of interest to the practicing physician have come from dermatologists. This is natural, since many of the clinical mycologic disorders commonly seen affect the skin but, of course, are not confined to it.

This small book on mycology too is written by a dermatologist and treats mostly of cutaneous infections. It emphasizes the ringworm group in keeping with an obvious attempt to give the most help where the average practitioner needs it oftenest. Probably too the author's experience has inclined him toward the division of space to subject matter adopted. The number of original illustrations seems to show this. These are excellently done and well reproduced. There is combined in this little manual a working knowledge of the laboratory aspects of the fungi together with a description of the clinical aspects of the diseases induced. Treatment too is given a fair consideration. A valuable part of the book is a table which summarizes succinctly both mycologic and clinical information about the important pathogenic fungi. There may be a question or two about the systems of taxonomy adopted for classification of the organisms, but the busy doctor will hardly be worried about this aspect. Perhaps a more serious criticism is the scant consideration given to immunology. The work, however, is evidently meant to provide an acquaintanceship with the field of mycology rather than for the advanced student. For this purpose the volume can be of service and may be recommended.

An Introduction to Clinical Perimetry. By H. M. Traquair, M.D., F.R.C.S., Ophthalmic Surgeon, Royal Infirmary, Edinburgh. With a foreword by Norman M. Dott, M.B., Ch.B., F.R.C.S. Fourth edition. Cloth. Price, \$6.50. Pp. 332, with 248 illustrations. London: Henry Kimpton, 1942.

There has been a general revision of Traquair's book, which first appeared in 1927, and eighteen new illustrations have been added. This edition follows the form of the three previous editions in that the first part contains chapters on normal fields, methods of examination and instruments available for field studies. In part II the author gives illustrations of typical fields, anatomy of the visual pathways and illustrative cases with fields demonstrating interruptions at various levels. There are special chapters on diseases of the choroid and retina, glaucoma, optic nerve diseases, the optic chiasm, the suprachiasmatic pathway and functional changes in the fields of vision. In the appendix he presents isopters for white and color in the normal field; the blind spot; anatomic relations of the visual pathway; the optic nerve sheaths; blood supply of the visual nerve path; other uses of the perimeter and a table of tangents for use with the Bjerrum screen. This book has been a guide for students and practitioners of ophthalmology, and the present edition upholds the author's reputation as a teacher of perimetry and ophthalmic neurology.

A Synopsis of Surgical Anatomy. By Alexander Lee McGregor, M.Ch., F.R.C.S., Assistant Surgeon, Johannesburg General Hospital. With a foreword by Sir Harold J. Stiles, K.B.E., F.R.C.S. Fifth edition. Cloth. Price, \$6.50. Pp. 710, with 696 illustrations by Dr. E. A. Thomas. Baltimore: William Wood & Company, 1943.

The reviewer of a treatise on anatomy must obviously confine himself to remarks concerning the manner in which the subject is treated. In this small volume McGregor has made a special effort to correlate the high points of structure, function, surgical diagnosis and surgical technic. In this he has succeeded very well. The numerous diagrammatic line drawings are so well chosen that without the aid of the text they convey to the reader much of the information set forth in the book. The first half of the treatise is concerned with the anatomy of the normal, the last half with anatomy of the abnormal. The latter division

includes congenital malformations, fistulas, diverticula and the anatomy of nerve injuries. Deserving of special commendation are the chapters on the anatomic bases of clinical tests, the anatomy of certain diseases (infections of the hand, dislocations, rare hernias) and the anatomy of surgical procedures. The author naturally presupposes a knowledge of descriptive anatomy on the part of the reader. The volume therefore does not serve as a textbook or a summary of the subject. On the other hand it is recommended for students in surgery and for interns and residents to peruse in connection with their daily work. To the surgeon it is highly recommended as a small reference volume for constant review in order to keep clarified the salient features of surgical anatomy.

The Anatomy of the Female Pelvis Including a Description of the Placenta and Its Formation and the Fetal Circulation. By C. F. V. Smout, M.B., Ch.B., M.R.C.S., Senior Lecturer and Acting Professor, Department of Anatomy, Sub-Dean and Tutor, Faculty of Medicine, University of Birmingham. With sections, in part I, on The Histology of the Female Reproductive Tract and a chapter on Ovarian Endocrine Function by F. Jacoby, M.D., Ph.D. Foreword by Sir Beckwith Whitehouse, Ch.M., M.S., F.R.C.S., Professor of Midwifery and Diseases of Women, University of Birmingham. Cloth. Price, \$8. Pp. 190, with 170 illustrations. Baltimore: William Wood & Company, 1943.

This monograph includes many colored illustrations. In general they are quite clear but the black and white ones are not. The author has included a chapter on endocrine function, a chapter on the placenta and one on fetal circulation. There are also chapters on embryology and histology. The latter two might properly be included in a monograph on anatomy of the female pelvis, but the other chapters have no place. Furthermore, in the chapter on the placenta the excellent studies of Grosser and Spanner have been omitted. The reviewer feels that the chapter dealing with the pelvic floor is the best.

Nutrition of the Dog. By Clive M. McCay, Professor of Nutrition, School of Nutrition, Cornell University, New York. Cloth. Price, \$1.50. Pp. 140, with 14 illustrations. Ithaca, New York: Comstock Publishing Company, Inc., 1943.

This small volume, by a professor of nutrition who is also a dog lover, does just what it set out to do. It is addressed to the intelligent layman wishing authoritative information about his pet's nutrition, and technical language is correspondingly minimized and explained. It is addressed to scientists not specializing in this field who have occasion to work with dogs, and key references to the newest as well as the older classic papers are included with each chapter. Perhaps, most of all, it is addressed to those concerned with dogs in their business—breeders, handlers and food manufacturers, and for them it provides an excellent guide on nutritional matters. Throughout the text, and explicitly in the first chapter, the author marshals evidence against the antivivisectionists and points out how experiments on dogs have benefited both dog and man. After a general introduction a chapter each is devoted to the dietary requirements of the dog for carbohydrates, fats, proteins, minerals and vitamins. Then follows a section on dog foods, with chapters on the modern commercial feeds, on their ingredients, on testing them and, finally, on practical feeding. The volume should contribute much to canine welfare, even though, as the author dammingly states, "The dogs of this country are, as a whole, probably better fed than the children."

A History of Tufts College Medical School Prepared for Its Semi-Centennial 1893-1943. By Benjamin Spector, M.D., Professor of Anatomy, Tufts College Medical School, Boston. Cloth. Pp. 414, with 142 illustrations. Boston: Tufts College Medical Alumni Association, 1943.

The book describes and documents in chronologic sequence some of the events that occurred at Tufts College Medical School from 1893 to 1943. During these years momentous changes in medical education occurred. The book makes no attempt to trace these changes or to define the position of Tufts College Medical School in these revolutionary developments. Parochial in its outlook, this volume may be of some interest to Tufts faculty, students and alumni but probably not to others.

La glomerulonefritis en la infancia. Por el Dr. Arturo Baeza Goñi. (Prólogo del Prof. Dr. Carlos Lobo O'Neil.) Paper. Pp. 316, with 28 illustrations. Santiago, Chile: Empresa editora Zig-Zag, S. A., 1942.

This comprehensive monograph on glomerulonephritis in childhood is entirely clinical, every one of the author's contentions being supported by clinical histories.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

EXAMINATION OF BLOOD AND URINE DURING SULFONAMIDE THERAPY

To the Editor:—At a recent medical society meeting the question was brought up regarding the responsibility of a physician who gives sulfonamides in the home for making periodic checks of the blood and the urine. An opinion on this matter would be appreciated.

A. E. Meinert, M.D., Winona, Minn.

ANSWER.—Whether or not a physician should make periodic examinations of the blood and urine in patients receiving sulfonamides at home is dependent on several factors. The more serious hematologic complications arising from sulfonamide therapy include acute hemolytic anemia and agranulocytosis, while the outstanding urinary abnormality is the suppression of the flow of urine. Fortunately, the foregoing hematologic complications have been rarely encountered. An acute hemolytic crisis is most generally associated with the administration of sulfanilamide, usually occurring after the drug has been ingested for several days. Acute hemolytic anemia may be suggested by the sudden appearance of icteric scleras and pallor of the mucous membranes. Agranulocytosis is a relatively uncommon complication of sulfonamide therapy but may be precipitated by any one of the commonly used sulfonamides. In general, agranulocytosis occurs after the second week of therapy. Therefore, if a physician elects to continue sulfonamide treatment of a patient longer than one week, it is practically imperative that the level of the blood leukocytes should be determined twice a week thereafter. At the same time, it would be highly desirable to perform a differential count of the leukocytes. Urinary tract complications occur with relative frequency following sulfonamide therapy. A few simple precautions carried out in the home may prevent their appearance. Some responsible person should be instructed to measure and record the daily intake of fluid and output of urine. Of an adult, the daily excretion of urine should exceed 1 liter. This person should also be instructed to watch for the appearance of hematuria and also should be acquainted with the manifestations of pain related to the urinary tract. An added precaution on the part of the physician should be the establishment of an alkaline urine by prescribing 10 to 15 Gm. of sodium bicarbonate daily when sulfathiazole, sulfadiazine or sulfamerazine are being administered. If these instructions and precautions cannot be carried out, the physician will have to assume the responsibility himself. Only in isolated instances are urine analyses necessary.

In summary, the sulfonamides may be safely prescribed in the home without the analyses of blood and urine by laboratory procedures. However, certain of these procedures become necessary if the usual therapeutic doses of a sulfonamide are being prescribed for longer than ten days.

SIMULTANEOUS ADMINISTRATION OF PENICILLIN AND BLOOD PLASMA

To the Editor:—What provision, if any, has been made to add penicillin to blood plasma for simultaneous solution and injection for war wounded? Are there any valid objections or possible incompatibilities?

Herman Goodman, M.D., New York.

ANSWER.—There are no incompatibilities between penicillin and blood plasma. The difficulties that would arise from adding penicillin to dried blood plasma for simultaneous solution would concern the question of the stability and deterioration of penicillin. Unless penicillin is refrigerated constantly in the dry state it may lose its potency rapidly. The use of penicillin at the same time at which blood plasma is given might be of advantage, provided it could be followed by repeated and regular injections of penicillin. If this is not done a single injection would probably be of little benefit, since it is excreted from the body at a rapid rate.

At the present state of knowledge it would not seem to be a practical procedure because of possibility of deterioration, inadequacy of a single dose and impossibility of regulating dosage. It would appear more practical to make separate arrangements for administering penicillin when its use is indicated.

TREATMENT OF BONE CAVITY AFTER REMOVAL OF TUMOR

To the Editor:—A man aged 69 developed a tumor of the upper end of the tibia which failed to be recognized by his adviser and was neglected by him until it was approximately 4 inches in diameter. It proved to be a giant cell tumor and was completely removed without destroying the integrity of the bone shaft and without entering the knee joint cavity, though there was but little to spare. The cavity has filled in by about one half to two thirds of the original space and is clean but has failed to fill in appreciably more for the last three months. Operation was done seven months ago. There is no pain or other disability nor serious difficulty in walking, but the cavity is becoming a nuisance to him. What is the accepted method of treatment for such a bone cavity with wide open mouth and clean surfaces? If a bone paste is indicated, what is the best composition for such paste. Any suggestions as to treatment?

R. H. Gilpatrick, M.D., Nantucket Island, Mass.

ANSWER.—Judging from the query, it may be assumed that the problem is a bone defect just below the knee; in other words, a cavity which is lined with granulating tissue. The time to use bone grafts to fill in such a defect left after the removal of a giant cell tumor is at the time the tumor is removed and not later. Any bone grafting procedure at a later stage would be doomed to failure. It would appear that the patient has ample bone left in the upper tibia for skeletal support, so a graft for strength is not necessary.

If the walls of the cavity are not too steep and the opening too small, one could place skin grafts on the clean granulation tissue with the hope of at least lining the cavity. Pinch grafts could be used in large numbers. A large split graft could be used by placing it on a mold made with dental wax. The skin graft must be tightly fitted over the mold and then pressed down into the cavity, thus holding the skin graft firmly against the granulation tissue.

It is doubtful that any bone paste would work in such a situation.

METHODS OF CONTRACTING UNDULANT FEVER

To the Editor:—What is your opinion of the source of undulant fever? Doctors in this section usually think of raw milk of goats or cows infected with Bang's disease. It occurs to me that a more likely source is meat, raw or only partially cooked.

E. J. Brooks, M.D., Dallas, Texas.

ANSWER.—Any material containing live *Brucella* organisms may be a source of undulant fever. Infection may take place through the broken skin as a result of handling infective materials or by way of the digestive tract as a result of ingesting infective foods. In the infected animal the *Brucella* organisms are usually found in lymph glands, the reproductive organs and the udder. If a person ate uncooked meat containing a diseased lymph gland or raw dairy products made from milk containing the organisms there is a possibility that infection would occur. No one has any information as to the percentage of cases that come from meat or dairy products. There is no way of obtaining such information.

LOCKING OF PENIS IN COITION IN DOGS

To the Editor:—The penile spines described in the answer to the query on page 267 of the January 22 issue of *The Journal* are a bit of folklore which should not be perpetuated in a scientific journal. Because the distal portion of the shaft (corpus cavernosum urethrae) in the dog's penis is stiffened by a bone and the proximal portion of the penis is splinted by a muscular prepuce, penetration is possible before tumefaction occurs. Once the penis is thrust into the vagina, tumescence causes swelling of the corpora cavernosa, which in the dog extends only a short distance up the shaft of the penis, and a large bulb is formed at the root of the penis, which catches inside the female vestibule and causes the locking mechanism referred to in the query. Carl W. Walter, M.D., Boston.

To the Editor:—In reference to a query appearing in *The Journal*, January 22, concerning sexual intercourse in the dog, the reply is not entirely factual. Veterinary physiologists describe the act as consuming fifteen to thirty minutes. The so-called spines referred to are the bulbous glands, a rounded enlargement behind the pars longa glandis and is part of the glans penis. Both the pars and the bulbous are composed of erectile tissue, and their cavernous spaces are largely venous in character and for this reason are slow in erection. However, when these sinuses are completely filled the bulbous glandis becomes large and dilates the posterior portion of the vagina, which is correspondingly large to receive it. Simultaneously the sphincter of the vagina contracts and the male is unable to withdraw the penis in the erect state. In the dog ejaculation is thought to take place after the bulbous gland has become enlarged and the organ cannot be withdrawn. However, there have been some successful inseminations in which withdrawal of the penis has resulted before the enlargement of the bulbous glandis. It is believed that the neutral prostatic secretion is the bulbous glandis. It is required in abundance to counteract the highly acid nature of the vagina and thus afford a viable medium for the spermatozoa when they are ejaculated.

MULTIPLE ECHINOCOCCUS CYSTS OF THE LUNG, LIVER AND ABDOMEN

COMMANDER EMILE HOLMAN (MC), U.S.N.R.
AND
PHILIP PIERSON, M.D.
SAN FRANCISCO

The diagnosis of hydatid disease in America, particularly in the Western sheep-raising states, no longer provokes surprise or elation in encountering a medical rarity. In certain localities in Australia,¹ Italy, Argentina² and Iceland hydatid disease receives the first consideration in diagnostic problems, whereas in this country it is usually offered last as a remote possibility. It may be confidently predicted, however, that its occurrence here will become more frequent and that in certain localities its presence must be suspected whenever unusual manifestations of hepatic or pulmonary disorders cannot be explained on other seemingly more rational bases.

The disease is most commonly found in areas where sheep pasturage prevails and where dogs are in intimate association with sheep and human beings. The cysts found in man, sheep, ox or hog represent the larval stage of the tapeworm *Taenia echinococcus*, which is harbored in the adult form in the intestine of dogs and related species. The egg liberated in the dog's intestine and transferred from dog to man, sheep or hog through intimate contact reaches the stomach and the small intestine, where the alkaline juices digest the egg membrane, liberating the embryo, which penetrates the wall of the intestine and reaches the liver and other organs by blood stream migration. In its new location the embryo is soon surrounded by a limiting membrane produced by foreign body reaction, within which a germinal layer is developed capable of producing innumerable brood capsules and daughter cysts. The life cycle of the tapeworm is completed when a dog or a member of related species eats the infected entrails or carcass of a sheep or hog and the larvae reach the intestine of the dog, where they mature into the adult tapeworm.

Although infection in man has been ascribed to eating infected berries growing in sections of the country

inhabited by infected moose and wolf,³ this must be very rare and most improbable.

As we become more conscious of its existence, greater care must be exercised in its diagnosis, and one must not be too easily led into a facile though false diagnosis on the basis of a positive complement fixation or a positive reaction to the intradermal test. Both have been found fallible, as experience sadly records. One of the always surprising features of the disease is the extent to which organs may be involved without subjective or objective evidence of its presence. Moreover, if one accepts Dew's⁴ estimate of the rate of increase in the size of a cyst as approximately 1 mm. a month, the disease has been present for years before asserting its presence either subjectively or objectively.

The following cases are presented for their unusual and instructive clinical features, and for the problems presented in their surgical removal:

CASE 1.—M. Y., a Basque sheep herder aged 53, born in the Pyrenees but a resident of this country for many years, had recently noted an increasing shortness of breath with some thoracic pain, but without cough, sputum or hemoptysis. The patient was short and overweight, the only obvious abnormality being a small epigastric midline hernia. Examination of the chest disclosed expansion equal but limited, dullness at both bases and particularly in the right midportion, but some also in the left midportion. The apexes were resonant. The breath sounds were diminished throughout both lungs, but no rales were heard. His heart was normal; the blood pressure was 132 systolic, 90 diastolic. There was no enlargement of the liver. The red cells numbered 5,590,000 per cubic millimeter, the white cells 11,000 without eosinophils, the hemoglobin 99 per cent. The patient was extremely sensitive to echinococcus cyst fluid introduced intracutaneously.

A roentgenogram (fig. 1) revealed two large cannon-ball shadows in the chest. Under fluoroscopic examination the exact site of the attachment of the cyst to the right parietal pleura was determined as being posterior to the 4th rib, and on the left the nearest approach to the cyst was found to be at the level of the 7th rib anteriorly.

After several days of high vitamin diet supplemented by vitamin concentrates, the first operation was performed on Sept. 10, 1938. Under cyclopropane anesthesia a portion of the right 4th rib between the posterior and the anterior axillary line was removed. The cyst was found to be firmly adherent to the parietal pleura. A large trocar was inserted, and the limpid, slightly milky fluid was aspirated and sent to the clinical laboratory in a sterile container for diagnostic use in other suspected cases. About 10 cc. of solution of formaldehyde diluted 1:10 was introduced in the cyst, and after a few minutes wait the cyst was incised and its contents, including many daughter cysts and the germinal layer, were easily separated from their attachments and sucked out with the sucker usually employed in tonsillectomy. Following the delivery of the cyst wall, apparently normal surface of lung, as disclosed by carbon particles normally deposited in alveoli,

was everywhere visible in the cavity formerly occupied by the cyst. The cavity was thoroughly wiped with gauze moistened with 10 per cent solution of formaldehyde and washed out with salt solution. A small catheter was placed in the cavity, emerging from the anterior end of the wound. No attempt was made to obliterate the cavity by sutures, as it

Fig. 1 (case 1).—Multiple echinococcus cysts of the lung in a sheep heifer aged 53

was easily collapsed by positive intratracheal pressure. The wound was closed in layers with interrupted sutures. When the last stitch was placed, a pronounced emphysema of the wound tissues prompted opening the previously clamped catheter. A steady stream of air escaped, indicating a fairly large opening into the bronchus.

Immediately after closure of the first wound, a second incision was made over the left 7th rib and a portion removed. The visceral pleura was everywhere free, as shown by a freely moving lung visible through the intact parietal pleura. Accordingly the 6th rib was removed, but again a freely moving lung was visible through the intact parietal pleura. Two large plain gauze packs were placed in the wound, compressing the area immediately over the cyst, with the expectation that the visceral and parietal pleurae would become adherent. The wound was closed without drainage, completely burying the gauze packs.

The catheter emerging from the cyst cavity on the right was placed under water, and for about twenty-four hours there was a free discharge of air through the tube, after which there was no further escape of air. About 1 ounce (30 cc.) of bloody fluid was discharged in the next twenty-four hours, at the end of which time the catheter was removed. A small drain of rubber tissue which had been placed at the angle of the wound was also removed after forty-eight hours had elapsed.

After operation the patient was somewhat dyspneic, and intranasal oxygen was administered for five days. On the 7th day the wound in the left chest discharged considerable blood tinged but clear fluid. A roentgenogram revealed a fluid level in the left lower chest. Under cyclopropane anesthesia the

Fig. 2 (case 1).—Appearance of lung following removal of cysts in two stage operation (see fig. 1).

following the aspiration of 20 cc. of cyst fluid, 20 cc. of 10 per cent solution of formaldehyde was injected into the cyst. After the lapse of a few minutes the cyst wall was incised between the traction sutures and its contents were sucked out, including the germinal layer lining the cavity. The walls of the cavity were wiped with gauze moistened with 10 per cent solu-

tion of formaldehyde and the cavity washed with saline solution. A small catheter was placed in the bed of the cavity and connected with rubber tubing leading to an underwater seal. The wound in the chest wall was closed tightly around the catheter with interrupted sutures. There was no escape of air at any time, and the catheter was removed on the third day. An uneventful recovery followed, with primary healing of both wounds (fig. 2).

The patient reentered the hospital for the repair of the epigastric hernia on July 23, 1941, three years later, at which time he was without symptoms of any kind referable to the chest, and roentgenograms were normal.

CASE 2.—B. R., a school girl aged 18 years, was operated on in March 1942 for appendicitis, when a pelvic cyst adjacent to the right ovary was accidentally opened and found to contain numerous daughter cysts. These proved on microscopic section to be echinococcus cysts. Postoperatively a pulmonary complication occurred which necessitated a roentgenogram of the chest. This disclosed rounded shadows above the right diaphragm, which were interpreted as being located in the lung. Complete recovery followed the appendectomy.

On May 19, 1942 the patient entered Stanford Hospital for further study and treatment.

Her past history revealed little illness except for the previous appendectomy. Despite a voracious appetite she had lost about 6 pounds (2.7 Kg.) in the three months preceding admission. As a child she had played constantly with 3 dogs.

Fig. 3 (case 2).—Echinococcus cysts of the liver projecting into the pleural cavity, but not into the lung, by penetration through the diaphragm.

Physical examination revealed few abnormalities. There were pleural crepitations low in the right anterior axillary line with suppression of breath sounds, but otherwise the lungs were clear. The liver and spleen were not felt, and there were no abnormal masses felt in the abdomen. Her temperature was 37.2 C. (98.9 F.), pulse rate 90, respiratory rate 20, blood pressure 106/72. The urine was normal, the red cells numbered 4,930,000 and the white cells 9,970, of which 59 per cent were neutrophils, 1 per cent eosinophils, 39 per cent lymphocytes and 1 per cent monocytes; the hemoglobin was 91 per cent (Sahli).

The echinococcus skin test was strongly positive, the immediate reaction showing a 10 mm. wheal, with pseudopodia, and a 50 mm. zone of erythema.

A pneumoperitoneum suggested abnormal contours both of the spleen and of the liver suggestive of cysts in these organs, but the masses seen in the roentgenogram of the chest still seemed to be in the lung (fig. 3).

On May 21 a thoracotomy was performed under cyclopropane anesthesia. An anterolateral incision was made in the sixth interspace without division or excision of the ribs, which were easily separated with the rib spreader. When the lung was severed from its attachments to the diaphragm, there were disclosed emerging through the dome of the diaphragm 3 separate cystic masses measuring 4 by 6 cm., 4 by 4 cm. and 3 by 3 cm. respectively. In an attempt to excise the largest, its wall was penetrated with the evacuation of clear fluid and many daughter cysts. These were all carefully sucked up by the aspirator. The diaphragm was incised, revealing at least 2 large cysts in the liver, which were the

source of the masses penetrating the diaphragm. Another thin walled cyst could be palpated on the under surface of the liver lateral to the gallbladder. One of the cysts in the liver was opened, and milky fluid and many daughter cysts were evacuated by suction. The lining of the cyst was also carefully removed in its entirety by suction, revealing a fibrous lined cavity in the liver at least 10 cm. in diameter. The walls of the cavity were wiped with gauze moistened with 10 per cent solution of formaldehyde and the cavity was washed with saline solution.

The second cyst in the liver was opened and similarly treated by evacuation with suction, removal of the entire cyst lining by suction, followed by the application of 10 per cent solution of formaldehyde to the walls of the cavity. This cyst was multilocular, about 10 cm. in diameter. The portion of the diaphragm through which the cysts had penetrated into the thorax was cleanly excised by an encircling incision through normal diaphragm. The two cavities in the liver were partially closed by chromic catgut sutures approximating their fibrous walls. Salt solution was introduced to fill any residual spaces. The phrenic nerve was crushed as it coursed over the pericardium, and the rent in the paralyzed diaphragm was easily closed with interrupted silk sutures. This closure of the diaphragm was easily made because of the collapse of the underlying two large intrahepatic cysts. Palpation and systematic examination of the accessible lung having revealed no evidence of other cysts, the incision in the thoracic wall was

Fig. 4 (case 2).—Appearance after operation, showing elevated diaphragm following excision of portion of diaphragm containing cysts and crushing of phrenic nerve (see fig. 3).

closed in layers. The lung was well inflated before closure, and drainage was not provided.

The postoperative course was without incident until the 6th day, when generalized abdominal pain, tenderness without much splinting, a chill, temperature of 40 C (104 F.) and a pulse rate of 140 caused considerable apprehension lest the subhepatic cyst palpated at the operation had ruptured into the abdominal cavity. Subsequent events proved that this had not occurred. The 7th day was a repetition of the 6th, but gradual improvement thereafter led to complete recovery and discharge from the hospital on the 17th postoperative day. The two days of fever were explained on the probable discharge into the abdominal cavity of salt solution which had been placed in the formaldehyde treated cavities in the liver.

Following an uneventful convalescence the patient reentered the hospital on August 10 for laparotomy and removal of the subhepatic cyst. In the interim she had gained about 8 pounds (3.6 Kg.) and felt very well except for occasional pains in the right flank. Physical examination revealed few abnormalities. The temperature was 36.8 C. (98.2 F.), pulse rate 70, respiratory rate 18 and blood pressure 120/70. The chest showed a well healed scar and the physical signs of an elevated paralyzed diaphragm. The abdomen was free from tenderness or abnormal masses. The urine was normal. The red cells numbered 4,490,000 per cubic millimeter and the white cells 8,050, of which 72 per cent were neutrophils, 4 per cent eosinophils, 1 per cent basophils, 16 per cent lymphocytes and 7 per cent monocytes. A roentgenogram of the chest (fig. 4) showed both peripheral lung fields clear and paradoxical movements of the right diaphragm.

On August 13 a short upper right rectus incision was made for exploration of the abdomen. In the right pelvis was a 2 cm. nodule (fig. 5b). After the incision had been enlarged this was found to lie just lateral to and firmly attached to the uterus, partially surrounded by omentum. It was excised with the radiocautery. In the left upper abdomen, lying between the

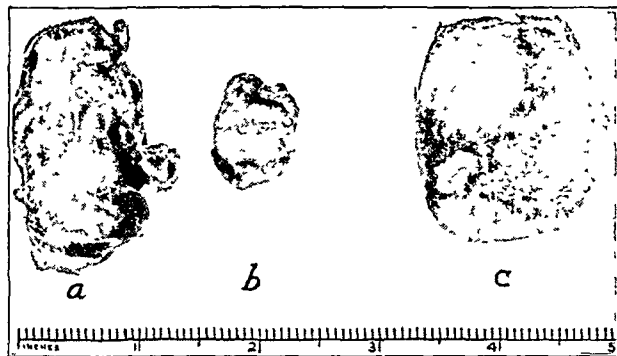

Fig. 5 (case 2).—a, echinococcus cyst removed from between left diaphragm and spleen; b, cyst excised from right pelvis; c, cyst excised from undersurface of liver.

spleen and the diaphragm, was a second 5 cm. nodule (fig. 5a), which was freed from the spleen with considerable bleeding. Its excision from the diaphragm left a small defect, which was closed with catgut sutures. These were covered by the spleen when it fell back into its normal bed.

A third 4 cm. sized cyst (fig. 5c) was removed intact from the under surface of the liver, leaving a raw liver surface, which was partially closed with a continuous catgut suture. A search of the abdomen for other cysts or masses was negative. Because of the possibility of bile drainage from the bed of the third cyst, three small cigaret drains were introduced to lie adjacent to the raw surface, emerging from a separate stab wound in the flank. During the operation 1,000 cc. of isotonic solution of sodium chloride was administered by hypodermoclysis and 500 cc. of blood by vein.

An uneventful recovery was followed by discharge from the hospital on the 12th postoperative day.

The following case is presented briefly because of the difficulties of diagnosis and because of erroneous conclusions based on a strongly positive reaction to the intradermal injection of echinococcus fluid.

CASE 3.—Mrs. E. P., aged 59, had been under observation at a naval hospital since Dec. 24, 1941 for cough, bloody sputum and pain in the right chest, when she entered a civilian

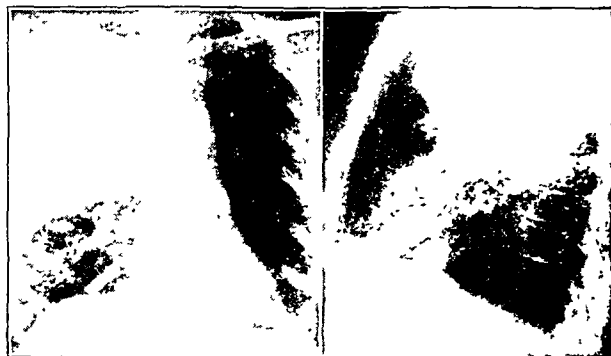

Fig. 6 (case 3).—Presence in chest on Aug. 10, 1942 of a large mass interpreted as being compatible with echinococcus disease, this diagnosis undoubtedly being influenced by a strongly positive intradermal test for echinococcus

hospital for further examination. Here the intradermal injection of echinococcus fluid produced a definite local urticarial reaction, elevation of temperature and pronounced focal signs and symptoms in the right chest. A roentgenogram (fig. 6) was interpreted as being compatible with echinococcus disease.

A review of the evidence, however, revealed certain significant findings: A roentgenogram in December 1941 (fig. 7) was interpreted as showing multiple metastatic nodules in the right upper lung field, the source of which had not been determined even after numerous other roentgenographic studies. A bronchoscopy on Jan. 5, 1942 had disclosed a "widening and thickening of the mediastinum," which was even more pronounced on April 17, when both primary bronchi were found

Fig. 7 (case 3).—Presence on Dec. 24, 1941 of multiple masses interpreted as being metastatic tumor nodules. A primary bronchogenic tumor was subsequently found. Appearance at this early date bears no resemblance to that of a primary tumor, although later studies might be so interpreted (fig. 6).

stenosed by flattening of their medial walls, strong evidence of a mediastinal neoplasm, probably metastatic. On Aug. 28, 1942, on a preoperative diagnosis of an intrapulmonary neoplasm, a short exploratory incision was made by resection of 4 cm. of the 4th rib posteriorly. A large firm, solid mass was found in the lung, biopsy of which disclosed a cellular tumor composed of sheets of large epithelial tumor cells, some of which showed an alveolar arrangement, with many mitotic figures. The diagnosis was an anaplastic carcinoma of the bronchus. As all evidence, roentgenographic as well as bronchoscopic, indicated a totally inoperable neoplasm, the wound was closed without attempting a pneumonectomy. The patient died four weeks later. A necropsy was not permitted.

COMMENT AND SUMMARY

1. Multiple echinococcus cysts may occur in the lung, in the abdomen and in the liver, almost without symptoms. In case 1, 2 large cysts of the lung which had probably been present for years produced only moderate dyspnea and some pain in the chest. In case 2, symptoms were minimal, despite multiple abdominal cysts in the pelvis and under the liver, as well as 4 cysts involving both diaphragms, and 2 large intrahepatic cysts.

2. Positive reactions following the intradermal injection of the echinococcus antigen cannot be relied on as clinching evidence in the diagnosis of echinococcus disease. Eosinophilia is not an invariable accompaniment.

3. In cases in which the cyst is in close relationship to the upper surface of the diaphragm, a large enough pneumoperitoneum should be given to explore the under surface clearly, since hepatic cysts may penetrate the diaphragm.

4. Cysts in the abdomen may be completely excised, particularly when surrounded by omentum or when appearing on the surface of other organs. The investing fibrous tissue, which is often partly calcified, permits excision without fear of entering the cyst. When calcification has occurred in the liver or lung, it is necessary only to suck out the chitinous or germinal layer of the cyst, leaving behind the calcified wall.

5. The removal of thin walled cysts of the lung by suction may be complicated by a pneumothorax, resulting presumably from small rents in the lung, unless

provision for the escape of air is made at the operation by the introduction of a small catheter into the bed of the cyst connected externally with an under water seal. This may usually be removed within forty-eight to seventy-two hours.

6. The problem of removal of the dangerous elements of a cyst may be met as follows: Withdrawal of about 30 to 50 cc. of the cyst fluid by aspirating syringe and reinjection of about 10 to 20 cc. of 10 per cent solution of formaldehyde. After several minutes a small incision is made in the cyst, and its contents are withdrawn with a large sucker. The contents include hooklets, daughter cysts and the germinal layer, which strips easily and is effectively removed with the sucker. The walls of the remaining cavity are wiped with gauze moistened with 10 per cent solution of formaldehyde and the cavity is washed out with saline solution.

7. Drainage or packing of the cyst cavity is not necessary and is definitely contraindicated to avoid secondary infection of a potentially incollapsible cavity. Except in the presence of pus due to a secondary infection which obviously must be drained, the cyst cavity may be filled with salt solution and the incision of approach may be completely closed without drainage.

8. Multiple cysts of the lung involving both sides of the thorax are most safely removed by two stage procedures.

THE ORGANIZATION OF A RED BLOOD CELL TRANSFUSION SERVICE

MAJOR EARL S. TAYLOR

Technical Director, American Red Cross Blood Donor Service
MEDICAL CORPS, ARMY OF THE UNITED STATES

WILLIAM THALHIMER, M.D.

Associate Technical Director, Red Cross Blood Donor Service
AND

WARREN B. COOKSEY, M.D.

Technical Supervisor, Red Cross Blood Donor Service
DETROIT

Attention has recently been focused on the use of red cell residues that are by-products of plasma production as a substitute for whole blood transfusions in the treatment of anemia.

The first work in the preservation of red blood cells suspended in isotonic solution of sodium chloride was reported by Rous and Turner¹ in 1916. Their experiments, however, were limited to animal transfusions. In 1918 Robertson,² in reporting the first blood bank transfusions in World War I, actually gave red cell suspensions rather than whole blood. Concentrated red cell transfusions were reported by Castellanos³ in 1937 and by Castellanos and Riera.⁴ Since 1940 there have been a number of reports by British workers on the practicality of giving multiple red cell transfusions both in the concentrated form and resuspended

in isotonic solutions.⁵ The more recent articles⁶ in this country confirm on the whole the results obtained and point out not only the saving in whole blood but also the superiority of red cell transfusion in the treatment of certain anemias.

The "Blood for Britain" (plasma) program (1940),⁷ a cooperative project of the New York chapter of the American Red Cross and the Blood Transfusion Association, was the first experience in this country with large scale blood procurement. The Presbyterian Hospital in New York City was one of the nine hospitals assisting in the work, and here the plasma was produced by the sedimentation method after three days. This made available in the hospital for the first time a large source of supply of fresh red cells. Plasma formerly had been but a by-product of "outdated" whole blood in the bank, and the "outdated" residual cells were not suitable for transfusion purposes. Scudder⁸ prepared and gave 227 red cell transfusions obtained from fresh citrated blood during this period. The suspensions were isotonic, usually 500 cc. of cell residual in 500 cc. of isotonic solution of sodium chloride. These transfusions were type specific. The reactions rate was comparable to the existing one at the hospital for whole blood transfusions.

During the past three years a number of the larger hospitals in this country, both military and civilian, have used red cell suspensions on a small scale for transfusion. The material has been available as a by-product of plasma production and has been offered as an additional blood bank service⁹ in these hospitals. Hoxworth¹⁰ at the Cincinnati General Hospital has provided red cell suspensions for transfusions as part of the regular service of the blood and plasma bank. Over 300 of these transfusions have been given there, with results in general agreement with the findings reported in the literature.

Almost immediately after the conclusion of the Blood for Britain project, the pilot center of the American Red Cross Blood Donor Service was established in New York City in February 1941.¹¹ The distance of the processing laboratory from the bleeding center, however, precluded any possibility of salvage of the red cells for transfusion purposes. With the rapid expansion of the Blood Donor Service, processing laboratories and bleeding centers at various points in the country came into closer proximity. However, even then large scale work with red cell suspensions was delayed until

a year ago, because of the primary necessity of concentrating all efforts on plasma production.

The salvage of red cell residues for transfusion purposes presented several problems to the Blood Donor Service not encountered in local blood and plasma banks. The blood was collected by a bleeding team at varying distances from the laboratory. The blood had to be transported to the laboratory and, after withdrawal of the plasma, the residual cells had to be resuspended and then shipped back to the blood donor center for distribution and use. The question arose whether significant change would take place in the cells because of the transportation. Further, the handling of the blood by three separate groups of people not only offered the chance for breaks in technic because of divided responsibility but also gave real opportunity for transcription errors. In order that the greatest possible plasma yield might be obtained, the blood is centrifuged at 2,100-2,400 revolutions per minute for thirty to forty-five minutes. What effect there would be on the fragility of the cells as contrasted to those obtained as a by-product of sedimentation methods or of slower centrifugation had to be determined. With the transportation and multiple handlings necessary, the problem of placing responsibility for the quality of the final product had to be clarified.

Because of these specific problems not similarly encountered in other work in this field, much of the previous work had to be repeated before it could be determined whether the results were applicable also to red cells treated as these must be.

Within the last year one (W. B. C.)¹² and later another of us (W. T.) have prepared and have given nearly 10,000 red cell transfusions. The majority have been type specific. The cells have been resuspended in pyrogen free isotonic solution of sodium chloride up to the original 500 cc. volume. The clinical results of this work are being reported in detail.¹³ In conjunction with this, studies on the sterility of the cells and the survival in vivo of the cells after transfusion have been carried out. The life of the cells in vitro as measured by degree of hemolysis and cell fragility in various types of preservative solutions has also been investigated. The particular response to this therapy in specific types of anemia has also been noted.

On the basis of these pilot studies a Red Blood Cell Transfusion Service has been organized, to be conducted by the technical staff of the American Red Cross Blood Donor Service. The technical operations of the service are under the supervision of the Division of Medical Sciences of the National Research Council through its Subcommittee on Blood Substitutes.

The Red Blood Cell Transfusion Service is operated locally through Red Cross blood donor centers, under the control in each center of its technical supervisor. It is being initiated only in those centers that are sufficiently near processing laboratories to allow close collaboration and where transportation between the center and the laboratory requires only a short time.

The service is conducted without cost to those being served. No financial profit is allowed to be made by any person or institution in connection with this service, since the project is supported financially by the American Red Cross as part of its blood donor service.

The service is tendered to military hospitals wherever requested and practical. It is to be extended to com-

munities when it is practical by furnishing red cell suspensions to selected physicians for use in hospitals of recognized standing for clinical investigation. The selection of physicians and hospitals is made as agreed on by the American Red Cross and the Division of Medical Sciences of the National Research Council, and the service may be made available only to those physicians and hospitals that enter into an agreement to carry out the prescribed methods and technic.

Final responsibility for the administration of the cells is assumed according to the signed agreement provided and is not transferable back to the American Red Cross Blood Donor Service to the Army, to the Navy or to the plasma processing laboratory.

The methods and technic prescribed for the preparation, storage and administration of the red blood cell suspensions are as follows:

1. The blood is withdrawn at the Red Cross center, according to the usual procedure.

2. The technician typing the blood receives the full bottle of blood properly tagged and accompanied by a donor record card and serology tube.

3. The name and number on the card, tube and bottle are crosschecked for transcription errors.

4. The original typing of the blood is done from the serology tube with two different lots of anti A and anti B typing serums of known high potency and the results are determined and recorded by two different technicians. Only type O bloods will be selected.

5. A yellow tag is attached to the bottle and the following information entered on the tag: (a) date of bleeding, (b) donor's serial number, (c) type, (d) expiration date.

6. A separate list giving the serial number and name for each bottle selected is made out and included with the bloods, which are shipped to the processing laboratory in a separate refrigerated container.

7. At the laboratory, the procedure is as follows:

(a) Serology tests are done and only bloods reported as negative are used.

(b) The bottle of cells is to be appraised for (1) plasma cell ratio (only full bleedings are utilized), (2) lipemia, (3) hemolysis, (4) mechanical defects, (5) breaks in technic, (6) presence of large clots. Bottles showing such defects are discarded.

(c) After centrifugation and withdrawal of the plasma, a sterile solid stopper is placed in the bottle.

The original white tag must not be removed from the bottle at the laboratory.

(d) Resuspension of the cells (either in the processing laboratory or in the outside laboratory; the procedure is the same in the 2 cases). Resuspension of the cells must be done in a dust-proof room with a filling buret and a second sterile solid rubber stopper inserted. Known pyrogen free isotonic solution of sodium chloride (or other solution approved by the National Research Council) is used as the diluent, and is added as soon as possible after centrifugation of the blood.

(e) Resuspended cells are returned in refrigerated containers to the blood donor center and the tags on the bottles checked with the list originally prepared. No pilot tubes are returned with the bottles.

(f) Bottles of resuspended cells are stored at 4 to 10 C. until distributed. Before distribution the cells are to be appraised for hemolysis and possible color change.

8. *Sterility.*—The dispensing laboratory or station must ascertain the sterility of all procedures at the outset and at regular intervals check the maintenance of this sterility. Sterility tests are to be done as follows:

(a) Five cc. of the cell suspension is placed in each of two tubes containing 20 cc. of a good nutrient broth containing dextrose.

(b) The tubes are incubated at 37 C. for fourteen days.

Fifty negative cultures are to be obtained at the outset and before any cell suspensions are distributed. Thereafter every fifth bottle is tested until three hundred negative cultures are obtained. As a routine procedure, one bottle is tested at random for each day of operation thereafter.

The appearance of contaminated bottles demands a thorough investigation of the causative factors and a cessation of activities until an adequate explanation is obtained. The procedure as indicated for sterility testing must be carried out before the cells are again released for distribution.

9. *Administration of the Cells.*—(a) All resuspended cells must be stored at 4 to 10 C. after distribution to the hospitals. Care must be taken not to let the temperature fall below the 4 degree level. If there is any question that freezing has occurred, the bottle of cells must be discarded.

(b) Cells must be used within five days of the date of bleeding.

(c) The cells are not to be removed from the original container until just before use.

(d) Resuspended cells should be observed at intervals for the appearance of hemolysis or any change in color of the supernatant fluid. If a violaceous or blackish red color appears, if there is any question as to the condition of the material or if any unusual odor is apparent, the cells must be discarded.

(e) The cells must be retyped and cross matched at the hospital immediately before use. A sterile pipet is to be inserted in the bottle and a specimen removed for this purpose. The cells must be given within five hours of the time the bottle has been entered.

(f) The cells are not to be dispensed directly from the original container. Immediately prior to administration they must be poured from the original bottle into the dispensing flask in order that gross clots or unusual odors may be detected.

(g) The cells must be filtered through four layers of 44 by 40 bandage roll gauze or used with a 100 mesh stainless steel filter placed in the administration set.

(h) The cells must not be warmed before use.

(i) If the entire contents of the bottle are not used, the remainder is to be discarded.

(j) The bottles in which the cells were contained must be returned to the Blood Donor Center from which they were distributed.

(k) The cells are not to be given to antepartum or postpartum patients unless there has been full appraisal of the Rh factor.

10. A report form for each bottle of cells is to be completed and returned to the technical supervisor of the American Red Cross Blood Donor Center dispensing the cells. The service will be discontinued if these reports are not properly executed and forwarded within a reasonable length of time.

As experience is accumulated, it is hoped that with the use of preservative solutions the service may be extended and the red cell suspensions transported over a considerable area with a longer dating. Combination of these red cells with other types of blood substitutes, such as gelatin solution, offer investigative possibilities.

SUMMARY

1. On the basis of pilot work with ten thousand¹⁴ red cell transfusions, it appears that this by-product of the plasma program for the armed services is suitable for transfusion use as a substitute, at least in part, for whole blood.

2. A Red Cell Transfusion Service is being extended from the two pilot blood donor centers to those centers which are proximate to the plasma processing plants. This service is conducted by the Blood Donor Service of the American Red Cross.

3. The service will be available first to Army and Navy hospitals and secondly to accredited civilian hospitals, without cost, for clinical investigation.

4. General rules as to the organization of the technical aspect of the service have been laid down.

5. Investigation is under way to extend the possible use of these red cell transfusions and further ascertain their value.

Detroit Blood Donor Center.

¹⁴ Since this article was submitted for publication, the total number of red cell transfusions given has increased to eighteen thousand.

USE OF SALVAGED RED CELLS

WARREN B. COOKSEY, M.D.

Technical Supervisor, Red Cross Blood Donor Service

DETROIT

AND

CAPTAIN WILLIAM H. HORWITZ

MEDICAL CORPS, ARMY OF THE UNITED STATES

When the American Red Cross Blood Donor Service opened its Detroit unit in November 1941 it was at once our desire to make use of red cell residues that were discarded after the plasma had been drawn off. However, it was not until July 1942, when Parke Davis & Company began to process plasma from the Detroit Blood Donor Center, that the opportunity presented itself. As there were no reports available on the use of cells which had been subjected to high speed centrifugation and few reports available as to the proper fluid for resuspending such cells, various studies were undertaken before these resuspended cells were used clinically. After the essential laboratory studies had been completed and nearly two hundred bottles of cells were administered to selected patients, approval was given by the National American Red Cross Blood Donor Service and the Surgeon General's Office of the Army to extend this program. On Jan. 1, 1943 the Detroit Red Cross Blood Donor Service began to deliver cells to fourteen nearby hospitals that agreed to carry out certain necessary regulations in the storage and administration of the cells. To date, 7,864 bottles of cells suspended in isotonic solution of sodium chloride (0.85 per cent) adjusted to a pH of 7.2 have been furnished these hospitals, and a follow-up study on 4,050 such cell transfusions has been completed.

From the beginning, the problem of sterility has been given serious consideration. We have cultured numerous bottles of blood and of resuspended cells without finding any contaminations. It did not seem feasible to continue to culture each bottle of cells in such a large program as this, since our laboratory studies and accumulated experience indicated that stored blood cells must be used in a relatively short time after the blood is obtained from the donor. It was found that, unless special diluents other than saline solution alone were used, the cells which were returned to us after high speed centrifugation could not be held for more than five or six days from the date of bleeding without showing considerable hemolysis or definite alteration in the fragility index of the cells.

When red cell suspensions were deliberately contaminated for the purpose of investigation, it was found that, occasionally within twenty-four hours of storage at 4 to 6 C., and almost always after forty-eight hours of such storage, the contaminated cells turned a dark red and the supernatant diluent showed a purplish red discoloration that was at once distinguishable from unaltered cell suspensions. Since the method of distribution which we proposed rendered impossible the use of these cells before forty-eight hours from the time of bleeding, it was decided that this gross macroscopic test could be used in lieu of actually culturing each bottle of cells. As the cells were diluted back to their original volume with isotonic solution of sodium chloride there was ample supernatant diluent for a careful inspection.

After resuspension, the cells were retained in their original bottles and were not opened until the final typing and cross matching tests were done at the hospital just before administration. The technicians in charge of the blood banks using these cells were instructed to discard any bottle showing abnormal coloration as well as bottles not used by the fifth day from the date of bleeding.

As has been shown by Mollison and Young¹ and by Denstedt,² the development of hemolysis in stored blood in vitro does not parallel the fate of stored blood that has been transfused. Consequently, before these red cell suspensions were released on a large scale, numerous patients were studied to determine the occurrence of hemolysis in vivo by estimating the icterus index on the recipient's blood before and for several days after transfusion of the cells. In addition, urinalyses were made for several days after cell transfusion to determine the presence of hemoglobin or any of its end products. In the 200 transfusions so studied there was only 1 case in which the icterus index was increased and in which abnormal hemoglobin products not present before the transfusion were found in the urine. In this instance 5 liters of suspended cells was given an Rh positive patient with an extremely grave anemia of pregnancy. She was subsequently given stored whole blood, which produced an identical reaction. This could not be explained on the basis of the age or condition of the cells. In this patient the hemolytic process subsided at the sixth month of pregnancy, and she was carried to term. It was the opinion of the hematologist that this patient had an unusual hemolytic anemia of pregnancy. In the follow-up study of 4,050 bottles of suspended cells furnished Detroit hospitals, no other instance of a hemolytic reaction was reported.

Previous reports on the use of red cells dealt with undiluted or packed cells,³ but this method has certain disadvantages. In the first place, as Watson pointed out, pressure may be required to administer packed cells through the standard 18 gage needle. With the additional volume provided by the diluent in resuspended cells, the gravity method of administration is preferable both for its simplicity and for its safety. Furthermore, packed cells, when resuspended in saline solution at the end of five days' storage, show greater hemolysis and are more fragile than cells resuspended in saline solution immediately after withdrawal of the plasma. As already mentioned in the discussion of sterility problems, it has been our experience that the appearance of an ample supernatant liquid above the cells is a most useful aid in indicating that a deleterious change has taken place in the cells. We do not believe that the extra volume of the saline diluent is important.

As shown by chart 1, salvaged cells which have been subjected to high speed centrifugation reacted differently when resuspended in the various standard intravenous solutions ordinarily considered as isotonic

to human blood. Five per cent dextrose in distilled water produced a complete hemolysis of these cells in a very short time. Five per cent dextrose in saline solution frequently produced complete hemolysis. Two per cent dextrose and 2 per cent and 5 per cent sucrose produced the same changes as 5 per cent dextrose. Alsever's solution, containing 0.80 per cent sodium citrate, 2.05 per cent dextrose and 0.42 per cent saline solution gave as good results as Denstedt's solution, containing 1.7 per cent citrate and 2.3 per cent dextrose. These special mixtures were far superior to saline solutions in preserving the cells for a longer period of time, as indicated by in vitro studies (chart 1).

In the table the studies of cell fragility with these various solutions are shown. It is seen that saline diluted cells stood up very well until the fifth day, when the fragility index increased very rapidly. While the Alsever and Denstedt suspended preparations started with a slightly higher fragility index, this index remained at a constant level until the tenth or the fourteenth day. Mollison and Young¹ and Denstedt² have shown that the fragility index does not always parallel the life in vivo of these transfused human red cells. Nevertheless these fragility studies have aided

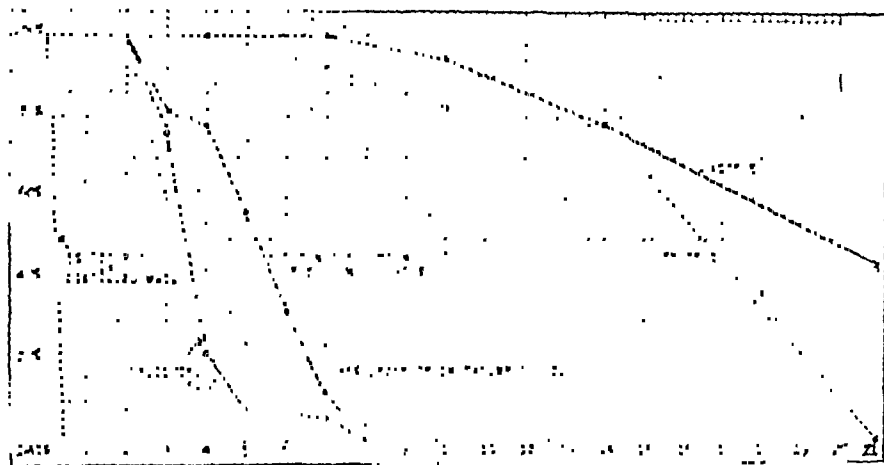

Chart 1.—Effect of various diluting solutions on hemolysis. Number of bottles (shown in percentages) which had supernatant fluid either "clear" or showing only a "trace" of hemolysis, by days from day of bleeding. All bottles had plasma withdrawn within twenty-four hours, and packed red cells were diluted within three or four hours after withdrawal of plasma. In the case of "undiluted" cells, hemolysis was tested by diluting with isotonic solution of sodium chloride, only on the day of testing. Each point on the graph represents observations on at least twelve bottles.

us in evaluating the various diluting solutions. We are now in the process of making studies of cell survival in vivo by the method of Ashby,¹ comparing saline diluted and Alsever diluted cells, and cells stored for various lengths of time.

When the amount of diluent added to packed cells was varied, so that its volume was one fourth of, one half

Effect of Various Diluting Solutions on Red Cell Fragility

Figures represent point of beginning hemolysis (in percentage of sodium chloride); each figure is an average of at least twelve tests.

Days.....	1	3	5	7	10	14	21
Saline solution diluted.....	0.40	0.49	0.50	0.67	0.72
Undiluted cells.....	0.48	0.52	0.68	0.71	0.76
5% dextrose in saline solution.....	0.52	0.56	0.63	0.72	0.76
5% sucrose in saline solution.....	0.51	0.50	0.57	0.58	0.62	0.74
.....	0.56	0.50	0.57	0.58	0.58	0.74

of or equal to the volume of cells, there was little apparent difference between the various preparations as measured by hemolysis and fragility studies. We have on several occasions pooled two or three bottles

of both diluted and undiluted cells of similar type and given them as one injection. We still prefer, however, to administer 500 cc. of saline suspended cells twice daily or three times daily when large amounts of blood are required. By this method ample blood can be administered quickly and the standard apparatus available in the various hospitals can be used with little change.

The number of reactions from red cell suspensions has been reported by other workers to be less than that of whole stored blood.⁵ In one hospital 413 separate resuspended cell transfusions were studied in 139 patients. Only a definite rigor followed by a rise of temperature was considered a reaction. In the 413 cell transfusions studied there were 9 definite reactions, a percentage of 2.1. These patients were also given whole bank blood at one time or another. When 342 bottles of stored whole blood were given to these same 139 patients, 12 reactions occurred, a percentage of 3.5. This would seem to suggest that there may well be a slightly lower percentage of reactions following saline suspended red cell transfusions than when stored whole blood is used. In another series of 629 saline suspended cell transfusions studied in three other

Detroit hospitals, reactions occurred in 3.0 per cent of the cases.

The red cell count and hemoglobin increase in 500 cc. of cell suspension administered was studied. A hemoglobin determination made by the Haden-Hauser method (16 Gm. of hemoglobin = 102 per cent) and a red cell count were taken approximately two hours before the cells were administered, and another hemoglobin and red cell determination was made twenty-four hours after the 500 cc. of cells was administered. These figures were averaged in 67 different cell transfusions given to 25 patients. The average hemoglobin rise from a transfusion of 500 cc. of suspended cells was 0.56 Gm. (3.75 per cent) and the average red cell rise was 206,700 cells. In the series of 629 saline suspended cell transfusions the hemoglobin rise varied from 0.46 Gm. in malignancy to 1.3 Gm. in obstetric cases to 500

cc. of cells administered. The red cells increase per bottle of cells administered varied from 123,157 in malignancy to 497,000 in obstetric cases.

As to the clinical improvement noted following cell transfusions, we can state that the results seem in every way similar to those from whole blood transfusions. Cell transfusions were not used in patients with significant hypoproteinemia, although, in a number of cases of debilitating illness with slight reduction in serum protein values, cell transfusions were used for economic reasons. The most significant and at times astonishing results from cell transfusions were seen in patients with severe anemia who were given 1,000 to 1,500 cc. of cells daily for two or three days. Several of these previously bedridden patients were able to walk around the ward after having received 2 or 3 liters of suspended cells in a period of two or three days.

We believe that much too often blood transfusions are given in quantities measured solely by the number of donors available; and not according to the need of patients for blood. When the storage areas in the

body are depleted of red blood cells, it may take several transfusions to fill these depots and be reflected in a proper rise in circulating red blood cells. With an unlimited supply of salvaged red blood cells available, it should always be possible to prescribe the amount of blood or cells really needed by the patient. Further-

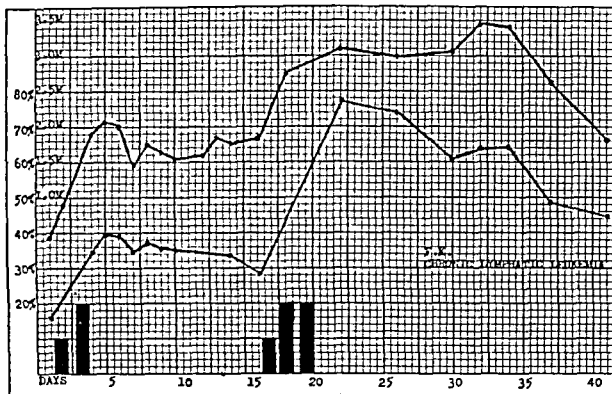

Chart 2.—Effect of red cell transfusions in a case of lymphatic leukemia. Upper line, red cell count; lower line, hemoglobin percentage.

more, recent studies have suggested that adequate amounts of blood given in a short period of time have a more beneficial and sparing effect on the bone marrow than the same total amount of blood when given over a period of several weeks.⁶

As has already been mentioned, red cell suspensions have not been used when pronounced hypoproteinemia is present. However, following acute blood loss of all kinds, in the later stages of burns and in numerous cases of debilitating illness, such as malignant conditions, tuberculosis, blood dyscrasias and severe chronic infection, red cell suspensions have proved of value. As would be expected, the number of reactions to cell transfusions in cases of blood dyscrasias, severe sepsis and malignant conditions is slightly higher and the hemoglobin and red cell count rise is slightly less than in patients with a simple acute or chronic blood loss.

In chart 2 is shown the hemoglobin (lower line) and red cell graph (upper line) of a patient with chronic leukemia with almost complete aplasia of the bone marrow. There were few platelets; the patient was bleeding from the gums and rectum and was orthopneic and unable to walk. His hemoglobin was too low to read accurately. Fifteen hundred cc. of suspended cells were given within eighteen hours, after which his bleeding ceased and he was able to walk about the ward freely. Several days later 2 more liters of suspended cells was given and he was discharged from the hospital. The very slow fall of his hemoglobin and red cell count over a period of twenty-six days without further transfusion is shown as an example of the prolonged beneficial effect of transfused cells under adverse conditions. In chart 3 is shown the graph of a patient aged 69 in a severe relapse from pernicious anemia who entered the hospital desperately ill with a lobar pneumonia of undetermined type. Two liters of suspended cells was given in thirty-six hours, together with sulfadiazine orally. Her blood picture was immediately restored to almost normal levels and was held there by the administration of liver extract. She made an uneventful recovery.

In the beginning of this work type specific cells were used, but as the project has expanded it was decided

to use only type O cells. In this way there is much less wastage of resuspended cells, and transcription errors are less likely to occur than when all types of cells are used.

The plan we are now using in the distribution of red cells at Detroit is as follows: On designated days a sufficient amount of blood is typed at the donor center to supply the number of bottles of O cells requested by the hospitals. This typing is done by two different technicians using two different preparations of high titer test serum and is done from the serology tubes only. The bottles of O blood thus obtained are individually and clearly designated with a special yellow tag. At the processing plant the routine procedure, including serology testing, is followed up to the point where the plasma is removed. As the bottles of O blood are collected in the plasma-removing room they are inspected for plasma cell ratio and color. After the plasma has been withdrawn, the cells are resuspended to their original volume in isotonic solution of sodium chloride. A sterile solid rubber stopper is inserted. The O cells thus prepared are delivered to the donor center on the day following their withdrawal from the donors. Each bottle still retains its original dated donor tag, as well as the special yellow O type tag. The red cell suspensions are transported in the portable refrigerators used by the Red Cross Blood Donor Service and on arrival from the laboratory are placed in our blood bank refrigerator. The following morning the bottles of cells are carefully removed and inspected for changes in color of both the supernatant liquid and cells as well as for mechanical defects. The bottles which pass inspection are then placed in special cardboard containers, and delivery is made to the participating hospitals. Most hospitals prefer delivery on Tuesdays, Thursdays and Saturdays, so that fresh cells are always available. For the small hospital, which may be only an occasional user, a few bottles are held at the donor center to be delivered as requested.

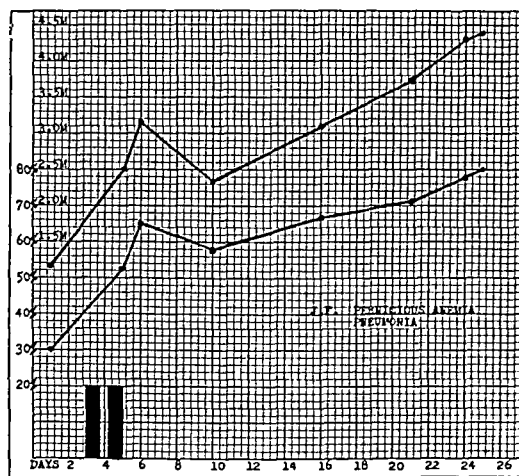

Chart 3.—Effect of red cell transfusions in a case of pernicious anemia with pneumonia. Upper line, red cell count; lower line, hemoglobin percentage.

The red cells used by the participating hospitals are furnished by the American Red Cross Blood Donor Service without charge, and no charge is made to any patient by the hospital except for the laboratory services of retyping and cross matching and for the use of administering equipment. The hospital assumes the full responsibility for the use of this

6. Doan, C. A.: Personal communication to the authors.

material. The laboratory technician in charge of receiving the cells from the Blood Donor Center is required to retype the cells and to cross match them with the recipient's blood. For this purpose suspended cells are obtained with a sterile pipet directly from the bottle just before administration. The technicians in all the participating hospitals are given mimeographed sheets of instructions as to the requirements of inspection for changes in color, and of adequate filtration, and as to the routine care of such stored blood. The cells must be filtered immediately before use through four layers of bandage gauze or must be given through a 100-200 mesh standard stainless steel blood filter placed in the administration set. Technicians are instructed to discard any bottle of cells which does not meet every specification. A simple report form is required to be filled out for each bottle of blood and returned to the Blood Donor Center.

A wartime program has provided this unusual opportunity to salvage the red cells remaining after withdrawal of the plasma from the blood that has been donated to the Army and Navy. It is probable that, with the extensive processing facilities now in existence for dried plasma and serum albumin and with a growing demand for such products, a continuation of this red cell salvage program may be possible, either through commercial plants or through community organizations.

SUMMARY

1. The cell residue obtained after centrifugation and removal of the plasma from serologically negative citrated blood collected at the American Red Cross Blood Donor Center in Detroit has been made available for use in the form of resuspended cell transfusions.

2. Isotonic, pyrogen free, sterile saline solution proved more satisfactory than a number of other solutions for preserving the centrifuged cells up to five days.

3. Careful aseptic technic preserved the sterility of the cells, as shown by controlled cultures at the beginning of the work and by the cultures of random samples at intervals thereafter. Any change to a dark red or violaceous color in the cells or supernatant fluid may indicate accidental contamination. If this occurred, or if for any other reason the appearance of the cells was questionable, they were discarded.

4. Rigid regulations as to retyping, cross matching, adequate filtration and time limitation were set up and adhered to by all users of the resuspended cells.

5. Nearly 10,000 bottles⁷ of resuspended cells were supplied to fourteen Detroit hospitals, and a careful follow-up study which was made of 4,050 of these cell transfusions showed very favorable clinical results.

6. The percentage of reactions was lower than that from whole blood transfusions in the same hospitals. The post-transfusion percentage of reactions from 413 saline suspended cell transfusions in 139 patients was 2.1, whereas from 342 transfusions of stored whole blood given to the same 139 patients it was 3.5.

7. The average hemoglobin and red cells rise in 500 cc. transfusion of suspended cells in 67 cases was 0.56 Gm. and 206,700 cells per cubic millimeter respectively.

8. Striking clinical improvement was noted in several severely anemic patients to whom a liter or more of suspended cells was given daily for several days.

9. Both type specific and type O cells were used at first, but later only type O cells were distributed. The

use of type O. resuspended cells is recommended to minimize transcription errors and to eliminate as far as possible any incompatibility reactions.

10. As in wartime, peacetime salvage of human blood cells would seem to be a logical sequel to the development of a plasma program.

RESUSCITATION OF THE DROWNED TODAY

FRANK C. EVE, M.D. (CAMB.), F.R.C.P. (LONDON)
HULL, ENGLAND

*In Seven Seas the victims drown;
Their cries for help imagination hears.*

A year ago our implicit faith in Schafer's almost sacrosanct method was shaken by Surgeon Commander Gibbens, who wrote that in the Royal Navy this method was rarely successful, although practiced by trained hands. The victim's chest felt to him "like putty," and ventilation of the lungs could not be effected. Doubtless this lack of response in bad drowning cases is due to lack of muscular tone, and this in turn is due to asphyxia of the nerve cells, situated between brain and spinal cord, which maintain tone and respiration. Now the main respiring agent is a thin sheet of muscle (the diaphragm) at the base of the lungs. In health this is pulled up into a dome by the elastic contraction of the lungs. When the diaphragm contracts, its dome is lowered and air is pulled into the chest. But when the diaphragm loses its tone progressively, as in drowning, it is pulled up by the elastic lungs into a position of extreme expiration. Schafer's method would then be useless, especially as it depends entirely on the elastic tone of muscles (no longer present) for inspiration when the pressure of the hands is taken off the patient's back. Schafer naturally assumed in 1908 that his method, which works well in normal conscious persons, would also work in the almost drowned, but this unfortunately is not true. What then are we to do about it?

In the first place we must not be hoodwinked by figures for the ventilation of the lungs derived from artificial respiration of conscious subjects. The only reliable imitations of a nearly drowned person are the newly dead cadaver and perhaps the deeply anesthetized person whose lungs have been overventilated to wash out carbon dioxide. In ventilation tests on the warm cadaver, Schafer's method yields only about 30 cc. (totally inadequate) and Silvester's method—of changing the size of the chest by extending the arms and then compressing the chest with them—yields 200 cc., which is probably just adequate. Two normal men anesthetized and their carbon dioxide washed out gave ventilations of 660 cc. for the Schafer method and 930 cc. for the Silvester method. Hence, of these two older methods which do not require apparatus, I would certainly start off with Silvester's method in a bad or pulseless case of drowning, though Schafer's method will probably succeed in milder cases. Silvester's face-upward method has the drawback that the flaccid tongue is liable to fall back and obstruct the airway, so that a second rescuer is needed to pull forward the tongue (or lax lower jaw). Schafer's technic is free from this objection, and mucus or water drains away better from the mouth in the prone position. Schafer's method is much improved if a

⁷ Since this paper was submitted for publication the number of transfusions given has increased to fifteen thousand

second operator (at the head end) lifts the extended elbows (and hence the chest) off the ground during inspiration (figs. 2 and 3). I read that this Nielsen modification had been adopted by the New York Emergency Service.

RESUSCITATION WITH BREATHING MACHINES

I can pass over the "iron lung," which is needed only in prolonged hospital cases of failure of respiration such as paralysis of the diaphragm by infantile paralysis or diphtheria. With the American partiality to machinery, there has been a remarkable vogue for various "suck and blow" machines for the drowned and in similar cases. In England they have not been favored. Professor Yandell Henderson strongly condemns them, but he still (in a recent letter) thinks

chair in the house so that the head-up and head-down posture could be alternated. Most fortunately they had a long rocking chair, to which a platform of folded blankets was added and the child tied on. Why not now alternate the tilt a dozen times a minute, so that the weight of the abdominal contents could push and

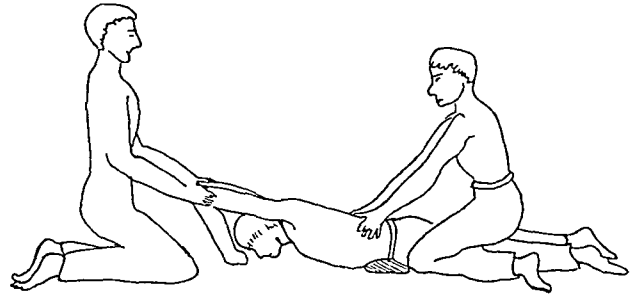

Fig. 2—Schafer-Nielsen method of resuscitation, inspiratory phase

pull the diaphragm up and down like a piston? This was done continuously by the devoted parents, completely relieving the child's breathing till the diaphragm paralysis passed off after two and a half days. She is still alive and healthy. In this interesting way I stumbled on a new method of resuscitation by rocking. With the expert aid of Dr. Esther M. Killick it was found (in the Leeds physiology laboratory) to be efficient, and at ten double rocks a minute with a tilt of 50 degrees to ventilate 600 cc. per rock (normal 500 cc.). This is ample ventilation: more would introduce the possible subtle dangers of acapnia (too little carbon dioxide in the blood).

ROCKING METHOD ADOPTED BY ROYAL NAVY

Faced by the failures of Schafer's method, Surgeon Commander Gibbens turned with relief to my rocking method, which worked by gravity and was independent of muscular tone. He adapted it to ships by fixing, under the middle of an ordinary stretcher, a pair of grooved wooden blocks to prevent slipping. On these it could be rocked 45 degrees each way, either on a trestle 34 inches high or on a loop of rope slung from the hammock hooks (fig. 1). The method has now (1943) been adopted preferentially in the navy and is fully described and illustrated in "First Aid in the Royal Navy," published at 2 shillings. Schafer's

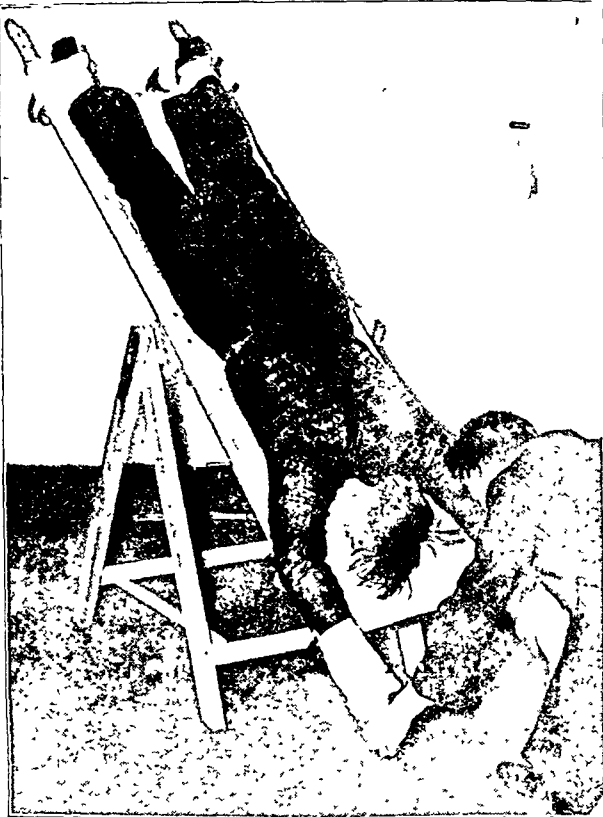

Fig. 1.—Rocking on a trestle. (Copyright by Surgeon Commander G. H. Gibbens, R. N. V. R., Fairlawn, Sidmouth, Devon, England)

Schafer's method adequate if aided by oxygen containing 6 to 10 per cent of carbon dioxide (seldom available for the drowned).

THE ROCKING METHOD

In 1932 I was called to a girl aged 2 years, propped up in bed, deathly pale and rapidly dying of the "death rattle" (mucus surging to and fro in the windpipe). I noticed that the diaphragm was not working, and inquiry elicited that the child had diphtheria six weeks previously but had been well till her breathing went wrong a few hours before my visit. In cases of "death rattle" I always tilt the patient so that the windpipe slopes downhill and the mucus drains into the throat, from which it can be swabbed. This tilt cured the death rattle in a few minutes, but I reflected that it would compress the lungs and thus conduce to pneumonia if continuous. I asked if they had a rocking

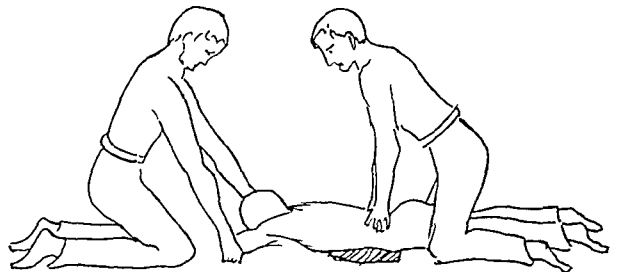

Fig. 3.—Schafer-Nielsen method, expiratory phase

method is used promptly and till rocking can actually begin. The patient is laid face downward and the ankles and wrists are lashed to the handles of the stretcher. The first head-down tilt of 45 degrees is maintained till no more water drains from stomach or lungs. After a few minutes a tilt of 30 degrees each way (ten times a minute) will be enough to ventilate the lungs. The advantages are that untrained operators

can work it instead of the relays of skilled operators needed by manual methods. It cannot injure ribs or viscera and is independent of muscular tone in blood vessels or diaphragm, in which respect unfortunately Schafer's method fails. Wet clothes can be removed during rocking and warmth applied.

In spite of many efforts I have not been able to get this method tested on the warm cadaver. But Dr. Macintosh, Nuffield professor of anesthetics at Oxford, has tried it out (1943) under deep anesthesia (in apnea) on Squadron Leader Pask, who was an anesthetist and realized that tests on conscious persons were useless. He nobly volunteered to be tested with proper recording instruments with ten double rocks per minute. The yields were Schafer 340 cc., Silvester 400 cc. and Eve 580 cc., with a tilt of 45 degrees each way. This experiment is considered to imitate the condition of a drowned man, but I doubt that tone in the diaphragm is completely lost.

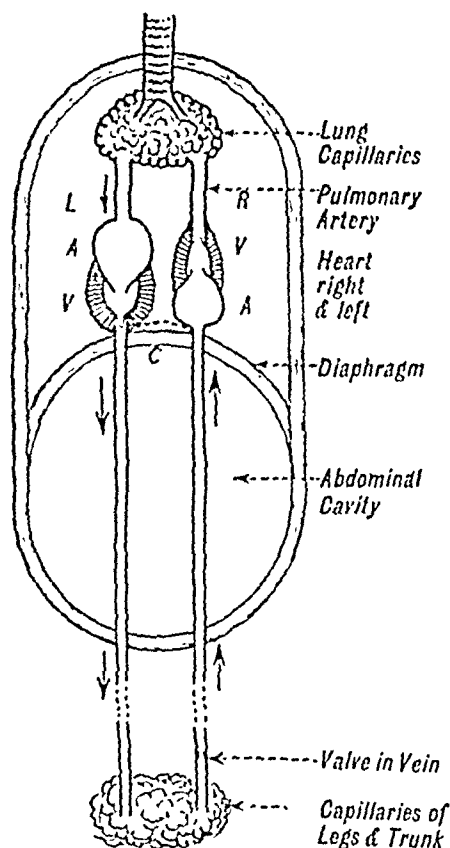

Fig. 4.—Diagrammatic representation of the circulation.

supported while the legs, arms and head hung limply. By swaying from their hips the two men rocked my 10 stone (63.5 Kg.) a dozen times a minute through about 40 degrees each way. Ventilation seemed adequate, for I did not need to breathe. They thought they could easily keep it up for a quarter of an hour or more. My modified Silvester method seems better still (not yet published). These manual methods have not been tried out but would be a long way better than nothing. Ashore a two-wheel builder's hand cart would serve for rocking, the victim's legs being lashed to the (abbreviated) pole handle. It could also carry blankets, macintoshes and life buoy to organized bathing places.

THE THREE ESSENTIALS OF RESUSCITATION

The term artificial respiration seems dangerously misleading because it focuses attention on ventilating the lungs. I submit that resuscitation is actually a trinity of ventilation, circulation and warmth directed to supplying warm blood, oxygenated by moving lungs, to the microscopic nerve cells which maintain respira-

tion and tone. These are situated where brain and spinal cord unite and can (I found) be paralyzed by cold and quickly revived by warmth. To illustrate what happens, Dr. H. W. Haggard was at hand to do artificial respiration when a man had a sudden fatal heart attack. He found he could ventilate the lungs normally at first, but after ten to fifteen minutes this became impossible. The nerve cells which maintain tone of the diaphragm had died of asphyxia and the elasticity of the lungs had drawn up the flaccid diaphragm into full expiration. Similarly in the apparently drowned, if too long unsuccored, the nerve cells will die of asphyxia, and then all hope is gone. Till then they may be revived by artificial respiration, seldom successful after trying for an hour, though rarely up to eight hours. The heart dies more slowly than the nerve cells, for after drowning the human heart has been revived by perfusing oxygenated saline solution, a baby's heart after several hours.

RESTORATION OF CIRCULATION

Probably in the future the merits of rival methods of resuscitation will be judged more by their effects on the circulation than on ventilation, which is so much easier to produce and to measure. For air in the lungs is useless unless the oxygenated blood is conveyed to the dying nerve cells. Up till now the effects of artificial respiration on the circulation have been crudely guessed from the alterations it produces in the pressures inside the heart of the newly dead man. Silvester's method, which opens up the ribs and then presses them tightly shut again, produces a pressure change of 26 cm. (of water) inside the dead heart: the Schafer method yields only 4 cm., increased to 22 cm. by the Nielsen modification. (The corresponding figures for ventilation are 280, 20 and 210 cc.) These (larger) pressure changes should help to restart the heart. It may be argued that Schafer's method should help by squeezing blood into the heart from the great veins in the abdomen. But it has been found (1939) in the Banting Institute, Toronto, that in drowned dogs (after artificial respiration and death) the venous side of the heart is overfull and the arterial side too empty. Bleeding was useless: amyl nitrite and carbon dioxide-oxygen mixture were helpful. Thus the apparent gain by the Schafer method seems likely to prove a disadvantage. The problem seems to be how to get the blood past the collapsed lungs and right side of the heart.

THE ROCKING METHOD AND THE CIRCULATION

To clear my own ideas I have found the diagram (shown in figure 4) most helpful and instructive. Since gravity in rocking affects only the longitudinal blood vessels, they can be represented as straight tubes: the arms and head (for clarity) can be omitted as they counterpart the legs and trunk: the tangled confusion of the heart can be simplified into two rubber syringes. Observe the one-way valves in the veins and heart, and particularly the broken line C. This indicates the coronary artery which carries oxygenated blood from the main artery through the actual muscles of the heart and so to join the blood flowing back into the lungs. If now we tilt the diagram (or the patient whose heart has stopped or nearly so) into the head-down tilt we see that the pressure of about 4 feet of blood in the arteries will slam shut the main (aortic) heart valve and have no option but to travel through the oxygen starved heart muscle. This should be invaluable in starting a stopped heart or restoring

a feeble one. Similarly the nerve cells of the brain and breathing center will receive blood rhythmically at a hydrostatic pressure which I calculate will be fully normal. The veins of the extended arms will acquire a reservoir of blood ready to fill the heart again when the legs are tilted down. Every drowning person is shocked, and in shock the venous side of the heart is said to be always starved of blood. In that case the head-down tilt will fill it and encourage it to beat and pump. That is why in shock we raise the foot of the bed: an empty heart pump evidently cannot work.

Now tilt the diagram (or patient) feet down. Blood falls from the lungs past the open valves of the left side of the heart into the arteries of the trunk and legs. Hence, in rocking, gravity propels the blood alternately in arteries and veins in the direction of the arrows; reflux is prevented by valves in the veins and heart. My faith that this will happen is confirmed by Sir Leonard Hill, the English physiologist, whose experiments (he writes me) showed that blood flow to the brain can be kept going by head-up and head-down positions alternated. For this and other reasons he considers my rocking method the best way of doing artificial respiration.

WARMTH

In victims of drowning the production of heat is minimal and the loss of heat maximal, especially from evaporation in a wind. Heat loss is visible only to the eye of the imagination and hence is often forgotten. Remembering that the revival of chilled nerve cells is our goal, I suggest hot bottles saddle bagged over the neck, or an electric shock cradle tied to the head end of the rocking stretcher. I read that a rigid corpse-like fakir was quickly brought to life, after being for ten days actually buried alive, simply by pouring hot water abundantly, chiefly over the head, neck and heart.

This seems worth trying for the drowned, who are already wet. Carbon dioxide is greatly used in resuscitation, as (normally) it is a splendid stimulant of the respiratory nerve cells when mixed 5 per cent with oxygen and inhaled. Yet Professor Macintosh tells me that he and several American anesthetists have recently abandoned its use because it is a dangerous depressant to the nerve cells of those at the point of death.

CONCLUSIONS

Resuscitation of the drowned is not merely working the bellows of the lungs but a fight to revive cold asphyxiated nerve cells by a circulation of warm blood oxygenated by moving lungs. Our old comfortable confidence in Schafer's method has been roughly shaken: Silvester's method is in many ways better, and the recent rocking method seems more promising still. Uncomplacently we must all "go to school" again. More experiments are badly needed: resuscitation is in the melting pot.

81 Beverley Road.

Estimating the Standing and Capability of a Man of Science.—There is only one sound criterion for estimating the standing and capability of a man of science, and that is the evaluation of the way in which he is regarded by his colleagues in his profession. If there were only one way of doing this, perhaps it might not suffice, but there are many. Membership in scientific societies of standing is important, wherever such membership is dependent on evaluation and election. Recognition by learned bodies is a guide.—Bush, Vannevar: *The Kilgore Bill, Science*, Dec. 31, 1943, p. 571.

CONCENTRATION RADIOTHERAPY OF CANCER OF THE LARYNX

A STUDY OF 413 CASES

MAX CUTLER, M.D.

CHICAGO

This is a report of 413 consecutive cases of cancer of the larynx observed by me between January 1931 and January 1943. The main purpose is to discuss the advances in the radiation therapy of laryngeal cancer with special reference to concentration radiotherapy and to analyze its bearing on the present day treatment of this disease.

It has been customary to separate cancer of the larynx into two main forms: extrinsic and intrinsic. There is, however, some confusion as to the exact definition of these terms, since they are used in the literature with different meanings depending on whether the particular classification is surgical or anatomic. According to the surgical classification, extrinsic carcinoma includes those arising from the aryepiglottic folds, pyriform fossae and postcricoid region as well as lesions arising within the laryngeal cavity which have spread outside the boundaries of the larynx. Obviously, lesions arising in the aryepiglottic folds, pyriform fossae and postcricoid region are not true laryngeal tumors but are lesions of the hypopharynx. The surgical classification found its justification in the fact that extrinsic carcinomas by definition are beyond surgical approach, whereas the intrinsic forms are considered operable. The anatomic classification refers to the primary site of origin of a lesion regardless of its subsequent extension. Thus, all tumors which arise within the larynx, regardless of their extension to the pharynx, remain by definition intrinsic. Because of this confusion and because many extrinsic carcinomas are actually carcinomas of the hypopharynx and not of the larynx, there are advantages in discussing carcinomas of the larynx with reference to their site of origin regardless of their subsequent extension. The classification used in this study is anatomic and histogenetic.

At birth the mucous membrane of the larynx, with the exception of the lingual surface of the epiglottis and the free borders of the vocal cords, is largely covered by cylindric epithelium. With increasing age, pavement epithelium gradually replaces the cylindric epithelium by a process of normal metaplasia. Pavement epithelium thus covers the borders of the epiglottis, the aryepiglottic folds and at times the false cords. The true cords remain covered by pavement epithelium throughout. Those sites in which the cylindric epithelium has been more abundant frequently give rise to tumors which are composed of cylindric nonepidermoid elements. Thus, in carcinoma of the false cords or the ventricular cavity the histologic type tends to be of a less hornifying variety and is usually composed of more undifferentiated nonepidermoid cells. In the true vocal cords, where pavement epithelium predominates, the type of epithelium is with rare exceptions that of epidermoid structure, and carcinomas in this region resemble the carcinomas of the cutaneous tissue and of the buccal cavity. These histogenetic factors have some bearing on the rate of growth and the type of lymphatic involvement as well as on the radio-sensitivity of the carcinomas arising at the various sites.

From the Chicago Tumor Institute and the Hines Veterans Facility, Hines, Ill., aided by a grant from the National Cancer Institute.

CLASSIFICATION¹

1. *Carcinoma of the Laryngeal Vestibule*.—This group includes two subvarieties: (a) carcinoma of the free borders and laryngeal surface of the epiglottis and (b) carcinoma of the false cords. The two varieties are discussed under the general term vestibular carcinoma because they are almost always involved together.

(a) Carcinoma of the free borders and laryngeal surface of the epiglottis generally produces a bulky ulcerated tumor which may grow to fill the entire

TABLE 1.—Classification of Cases According to Site of Origin

Type	No. of Cases	Per Cent
Vestibule (false cord and epiglottis)....	193	47
Ventricular cavity.....	26	6
True vocal cord.....	184	45
Subglottis.....	4	1
Origin undetermined.....	6	1
Total.....	413	100

laryngeal vestibule. The epiglottis itself may be partially destroyed. Anterior extension may result in tumefaction of the soft parts between the hyoid bone and the superior border of the thyroid cartilage. A second form of epiglottic carcinoma appears as a smooth, rounded, domelike swelling of the laryngeal surface of

the cord and extends anteriorly. Further extension anteriorly occurs either in the form of a thin layer of carcinoma extending along the superior and free borders of the cord or by an ulcerated destructive invasion of the cord itself. Extension then occurs to the anterior commissure and across the midline to the opposite cord. As the lesion extends posteriorly it involves the rich lymphatics in that site, which results in more rapid spread to the subglottic area, false cords, ventricle and aryepiglottic folds. In the beginning the clinical course is very slow.

4. *Carcinoma of the Subglottic Area*.—This type is probably more common than has been generally supposed. Many subglottic carcinomas have been regarded as downward extensions of carcinomas arising in the true cords. In this study only 4 cases have been identified, but it is probable that the incidence is considerably higher. Tomograms should prove of help in identifying this type. Subglottic lesions spread upward to involve the undersurface of the true cord and extend in all directions, involving adjacent cartilage. Since these lesions originate in a silent area, they do not give rise to early symptoms. Biopsy is difficult, and several attempts may fail to yield a positive diagnosis. The disease is nearly always more extensive than clinical examination discloses.

TABLE 2.—Age Incidence

Type	No. of Cases	Range of Ages	Average Age	Age Groups							
				10-19	20-29	30-39	40-49	50-59	60-69	70-79	80-89
Vestibule (false cord and epiglottis)....	193	32-78	52.1	0	0	11	77	65	32	8	0

Subglottis.....	4	19-65	51.7	0	0	0	7	1	1	0	0
Origin undetermined.....	6	42-50	46.5	0	0	0	5	1	0	0	0
Total.....	413	19-81	52.2	1	1	22	177	123	67	18	4

the epiglottis projecting into the vestibule. Ulceration may not be visible until late. A third type of epiglottic carcinoma arises from the free border of the epiglottis and spreads anteriorly into the vallecula.

(b) Carcinoma arising from the false cords tends to remain confined to the supraglottic region and often extends to the preepiglottic space. Extension to the true vocal cords results in intermittent hoarseness.

Carcinoma of the laryngeal vestibule has a tendency to grow rapidly and extend widely both by direct invasion and by lymphatic spread. This form is generally composed of undifferentiated cells and is comparatively radiosensitive.

2. *Carcinoma of the Ventricular Cavity*.—These tumors grow silently within the ventricular cavity without producing symptoms or signs over long periods. A sudden attack of dyspnea may be the first indication of disease. Laryngeal examination may disclose only a smooth elevation of the ventricular band without ulceration. When the lesion projects into the laryngeal lumen, biopsy of the papillary projections may be made without difficulty; however, when the tumor does not project into the laryngeal lumen biopsy is exceedingly difficult and often gives repeatedly negative results. The cells are generally undifferentiated, with a tendency to widespread invasion.

3. *Carcinoma of the True Vocal Cords*.—This type composes the majority of endolaryngeal tumors. The lesion begins in the midportion of the free border of

Table 1 shows the classification of the cases.

Stage of Disease: In 26 per cent of the 413 cases cervical adenopathy was present on admission to the hospital. The incidence of adenopathy in the different types was as follows: true vocal cords 7 per cent, ventricular cavity 19 per cent and vestibule (false cord and epiglottis) 45 per cent. Of 167 cases of carcinoma of the true cords in which the mobility of the cords was noted the cords were freely movable in 26 per cent, partly fixed in 26 per cent and completely fixed in 48 per cent. Of the 193 cases of vestibular carcinoma, 45 per cent were accompanied by cervical adenopathy.

Age: The average age among 413 patients was 52.2 years. The youngest was 19 years, the oldest 81 years.

Table 2 shows the age incidence according to decades. Symptoms: Dyspnea, pain, dysphagia and hemorrhage characterize lesions arising in the epiglottis. Intermittent hoarseness is a common symptom in lesions of the false cord and is generally due to pressure of the growth on the true cord rather than to invasion of this structure. The most striking symptom of carcinoma of the false cords is dyspnea. Dysphagia occurs when the lesion extends posteriorly and involves the pyriform fossa. A sudden attack of dyspnea in the absence of any previous warning may be the first indication of a carcinoma arising in the ventricular cavity.

Hoarseness is by far the most important and most common symptom of carcinoma of the true vocal cords. It occurred in 95 per cent of 185 cases in this series. Hoarseness occurs earlier when the lesions arise anteriorly and on the free margin of the cords. Pain

1. This classification is based on the one used in the Curie Institute of Paris.

and dyspnea are late symptoms. Table 3 shows the incidence and average duration of symptoms in the different forms of laryngeal cancer.

Biopsy: Biopsy was performed routinely in all cases of suspected laryngeal cancer. No effort was made to grade the specimens, although the microscopic examination included an estimate of the degree of cellular differentiation and anaplasia.

RELATION BETWEEN MICROSCOPIC STRUCTURE, PROGNOSIS AND RADIOSENSITIVITY

A radiosensitive tumor may be defined as one which can be completely sterilized without radionecrosis of the surrounding normal tissues. Since the property of radiosensitivity is a matter of degree and is intimately related to the efficiency of the treatment, it is impossible to draw a fine line of division between radiosensitive and radioresistant tumors.

The radiosensitivity of a tumor is intimately related to numerous factors: histogenetic, histologic, gross anatomic and constitutional. The underlying biologic phenomena are not at all understood. Clinical and pathologic experience emphasizes the inadequacy of microscopic structure alone in predicting radiosensitivity. The ultimate criterion and only absolute test of

treated by irradiation. Experience supports this view. It is my belief that when done by a pathologist especially experienced and skilled in this field, histologic grading has a value, but it must be interpreted broadly in relation to the clinical picture and in the light of modern radiation therapy.

The view that the presence of adult squamous keratinizing features in the biopsy indicates radioresistance has become entrenched in the literature on laryngeal cancer. This statement is usually followed by the deduction that such lesions, being radioresistant, should be treated by surgical intervention and not by radiation therapy. One obvious source of error is that a biopsy is frequently not a reliable index of the exact histologic composition of the lesion; thus, when a pathologist submits a diagnosis of squamous carcinoma from examination of a small fragment of tissue on a single biopsy he bases his report on the presence of adult, differentiated squamous features in the specimen submitted to him. If he had more tissue available, he might find undifferentiated elements or even a preponderance of such elements. In other words, the usual biopsy of a lesion in the larynx is wholly inadequate to permit an accurate estimate of the degree of differentiation. Multiple biopsies help to overcome this

radiosensitivity of a tumor is its clinical behavior under treatment. Because of numerous exceptions, it is hazardous to apply general rules to specific instances.

Many pathologists and surgeons believe that there is a relation between the degree of anaplasia and the results after surgical intervention in cases of cancer of the larynx, and some clinicians are influenced by the histologic grading in deciding between surgical operation and irradiation for certain operable intrinsic carcinomas of the larynx. The relation between the microscopic structure in the biopsy and radiosensitivity is even more complicated and is also highly controversial. The view that the histologic structure is of minor importance and of limited value in estimating radiosensitivity and determining the type of treatment is shared by numerous writers (Kriegsmann,² Harris and Klemperer³ and others).

It has been noted that when the cells are uniformly small and undifferentiated, especially when they exhibit a convoluted plexiform arrangement, the lesion is usually relatively radiosensitive, even though one finds interspersed islands of adult differentiated squamous elements with pearl formation. This microscopic structure is often found in lesions originating in the false cords and epiglottis. I am not certain whether this histologic type ever originates in the true vocal cords. This structure is usually classified as grade 3 or 4 and interpreted as being more malignant and hence better

difficulty but do not solve it completely. Another obvious source of error relates to the treatment.

In view of the steady increase in the effectiveness of irradiation, it is obvious that the terms radiosensitive and radioresistant, expressing relative qualities, must alter their meaning. Lesions that were radioresistant to the old type of irradiation used many years ago are radiosensitive to the methods used today. Thus, the conception that adult keratinizing squamous carcinoma of the larynx is radioresistant and hence not curable by irradiation is no longer tenable. Schinz and Zuppinger⁴ in 1937 reported favorable results of irradiation in 25 cases of adult squamous carcinoma of the larynx, and the observations now presented leave no doubt on this question. The experience described permits the definite conclusion that adult squamous carcinoma is not radioresistant to adequate external irradiation and is curable by adequate radiation therapy without radiation necrosis, provided the cords are not completely fixed.

Treatment.—Table 4 shows the disposition of the 413 cases of laryngeal cancer. Under the heading "inadequate irradiation" are included cases in which a full course of irradiation was not administered for one or more of the following reasons: (a) poor general condition, (b) advanced disease, (c) intercurrent disease resulting in interruption or cessation of treatment and (d) treatment before 1938 by technics which, according to present standards, must be regarded as having been wholly inadequate.

PROGRESS IN RADIOTHERAPY

The divided dose technic, generally known as the Coutard method,⁵ or some modification of it is the most prevalent form of roentgen treatment now in use. So much confusion surrounds the use of the term "Coutard method" that an effort to clarify it may be desirable. First, it should be pointed out that Coutard has never adhered to a rigid technic or to a single principle of treatment. The technic to which the term "Coutard method" is generally applied is based on the use of moderate daily doses of roentgen rays until a pronounced reaction in the mucous membrane and skin is produced. Decided variations in daily and total doses and in intensity of the reactions are included in technics described as the "Coutard method." After using a treatment time of thirteen to sixteen days for several years, Coutard prolonged the time first to eighteen days, then to twenty days and finally to twenty-five days, using daily doses of 400 and 300 roentgens. Several years later he prolonged the time still further to thirty, forty and fifty days, with a corresponding reduction in the daily dose to 250, 200 and 150 roentgens. In addition to varying

of treatment is eighteen days. In selected cases the treatment is given in two cycles.

Voltage.—Experience with the use of voltages higher than 200 kilovolts (400,000 to 1,000,000) is gradually accumulating, and certain advantages of higher voltage have been observed and recorded; but, so far as I know, there is no published report of a comparison between the use of 200 kilovolt roentgen rays and the use of higher voltages based on comparative clinical studies in which voltage has been the only variable factor. Not until such studies are available will it be possible to draw definite conclusions. Studies of this type are under way. In the meantime, 400 kilovolt x-rays are preferred, and this voltage was used in these observations.

Roentgen Intensity.—In the development of the new technic, intensities varying from 3 to 10 roentgens per minute have been used. Serious injury to the connective tissue and blood vessels has been avoided, and it is probable that the use of low intensities has been an important factor in safeguarding the normal structures. It would probably be unsafe to use this technic with high roentgen intensities.

the total treatment time and the daily dose, Coutard has explored various other methods, including preparatory treatment, supplementary treatment, periodicity and treatment of the tumor bed with protection of the tumor. It is obvious, therefore, that the use of the term "Coutard method" without specifications is indefinite and misleading.

Since 1938 efforts have been under way in the Chicago Tumor Institute and the Hines Veterans Facility to extend the effectiveness of external irradiation to the more radioresistant lesions which had failed to respond to the former methods of roentgen and radium therapy.

THE METHOD OF CONCENTRATION

One principle of irradiation soon arrested attention. The new method was called concentration radiotherapy. The principles and technic were described in 1941.⁶ The basis of this technic is the use of large daily doses over a comparatively short period (nine to twelve days) and a total dose sufficient to produce an "epithelium" and usually also an "epidermite." In one series of cases the daily dose is increased as the size of the port is diminished. For advanced extrinsic lesions the period

Fields.—In the treatment of cancer of the larynx, one or two fields may be used. As a rule, the peripheral portions of a lesion are more radiosensitive than the central portion, at or near the point of origin. Many carcinomas regress under external irradiation and leave a central unsterilized resistant remnant, which under some circumstances is best treated with a sharp, intensive irradiation by the interstitial method. Based on the belief that the central portion of a carcinoma is more resistant and therefore requires more intensive irradiation, a technic has been developed in which the size of the field is gradually reduced as the daily dose is gradually increased. If the supposition is correct that the periphery of a tumor is more sensitive than its center, this technic permits a more efficient distribution of the irradiation. Radiation energy, which is so often wasted on the normal tissues in the periphery of a tumor, is conserved by means of this technic for the treatment of the central, more resistant, portion, which is generally the site of recurrence. At the same time the normal structures are protected from unnecessary injury. This technic is especially suited for lesions which are small and comparatively radioresistant. In the treatment of intrinsic cancer of the larynx, I generally begin with a field of 48 square centimeters. This is reduced gradually to 12 and sometimes to 6 square centimeters. Great

6. Cutler, Max: Concentration Method of Radiotherapy for Cancer of the Mouth, Pharynx and Larynx, *J. A. M. A.* 117: 1607 (Nov. 8) 1941.

precision is necessary with the use of such small fields. The apparatus is provided with a device for centering the rays and a diaphragm; these permit accurate localization. Great care must be taken in the immobilization of the patient, and the field must be checked during the treatment.

Time (total treatment days).—For many years efforts have been made to determine the optimal time over which a given cancer should be irradiated. Regaud's original experiments with rams led him to suggest a total period of twenty to twenty-five days, but his later experiments suggested a treatment time of ten days. One highly important fact emerges from this experience in radiation therapy—namely, that within certain still undefined limits the more radioresistant the lesion is, the shorter must be the treatment time and the larger the daily dose. A superficial papillary carcinoma of the true cord, for example, can be sterilized with 6,000 roentgens given in small daily doses over a period of forty to fifty days. A carcinoma of the true cord which has infiltrated the underlying muscle and caused a partial or complete fixation of this structure as a rule cannot be sterilized by this method, but in a certain proportion of cases such a carcinoma can be sterilized when 6,000 roentgens is given over a period of twelve days or less. It seems as if the more radioresistant lesions require not only an adequate total dose but an adequate daily dose. In other words, an adequate total dose distributed over a period of such length that the daily dose falls below a certain level fails to sterilize the more radioresistant carcinomas. Different total treatment periods, varying between four and eighteen days, are being tested. The treatments are given twice daily and on consecutive days. The optimal period has not yet been determined.

Daily and Total Doses.—One of the questions that arises with regard to dosage is whether the more radiosensitive forms of cancer should be treated with smaller total doses than the more resistant types. According to my experience, generally speaking it is hazardous to administer less intensive treatment to a supposedly more sensitive lesion. There are exceptions to this rule. It seems safer to treat all lesions on the assumption that they belong to the more radioresistant variety. Thus one approaches the irradiation of a cancer on the basis of the maximum treatment that can be safely tolerated by the patient and by the normal tissues surrounding the growth.

Telecurietherapy (10 Gm. radium bomb).—The apparatus for telecurietherapy contains 10 Gm. of radium and is used at a distance of 12.5 cm. The ports vary from 10 cm. in diameter to 4 square centimeters. An effort is under way to determine the comparative value of telecurietherapy and roentgen therapy. All factors that can possibly be controlled are made comparable, so that the principal variable factor is the quality of the rays. Lesions of the mouth, pharynx and larynx are selected for their similarity as to site of origin, extent of disease and structure. Such comparable lesions are treated by the two methods in order to determine the comparative results. All that can be said at this time is that telecurietherapy is a highly useful method of irradiation and some interesting results have been obtained, especially since the "method of concentration" has been employed.

Thirteen patients with carcinoma of the true cord in which the cord was not completely fixed were treated with telecurietherapy; 11 of them are free from disease.

Lederman and Mill⁷ have reported 15 cases of carcinoma of the larynx treated with telecurietherapy and observed for five years after treatment; 7 of the patients are alive and well.

Present Technic.—After tests of numerous variations in the technic of external irradiation using the principle of concentration, several methods have crystallized which seem to be the most effective so far. Each technic is applicable to a certain type of laryngeal cancer as regards location and extent. These technics are in no way considered as final but are presented as one stage in the progress of these studies. Each of the three technics will be illustrated by a case report.

1. Roentgen therapy, 400 kilovolts, eleven consecutive treatment days, single field, increasing dose, diminishing port, total dose 5,700 roentgens:⁸ This technic is used for carcinoma of the true cord or early carcinoma of the false cord. The following case presents the details:

CASE 1.—A man aged 38 presented an ulcerated lesion occupying the left true cord, touching the anterior commissure and almost reaching the posterior commissure. The lesion was bulky and extended into the ventricle of the larynx, onto the left false cord and subglottically. The left hemilarynx was almost completely fixed; the left arytenoid was partly fixed. The right hemilarynx was normal. Biopsy showed the growth to be a squamous carcinoma. He was given roentgen treatment from June 15 to June 26, 1942, with the following factors: 400 kilovolts, 5 milliamperes, filtration 5 mm. of copper, distance 84 to 115 cm., single left lateral port 5 by 5 cm. gradually diminished to 3 by 3 cm., intensity 4 to 3.3 roentgens per minute. Two equal treatments were given daily beginning with 100 roentgens twice a day and increasing to 425 roentgens twice a day, a total dose of 5,400 roentgens, measured on the skin.⁹ After a twelve day interval the following supplementary treatment was given to the opposite side of the larynx: 500 roentgens twice daily for two days through a 3 by 3 cm. port (dose 2,000 roentgens, grand total 7,400 roentgens). The patient acquired epithelitis and epidermite. The lesion disappeared slowly, no longer being visible five weeks after the end of the main cycle of irradiation. There was no evidence of disease eighteen months after treatment; the voice was normal, and the larynx had a normal appearance. The lesion was much too advanced for laryngofissure and would have required total laryngectomy, a procedure that had been advised by several laryngologists. The patient was a lawyer and public speaker; he was psychologically unsuitable for laryngectomy and, in fact, had refused this procedure.

2. Roentgen therapy, 400 kilovolts, interrupted method, ten treatment days, two fields, increasing doses, diminishing ports, dose 7,700 roentgens:¹⁰ This technic is used in treatment of more advanced intrinsic carcinomas of the larynx in which the advantages of the therapeutic test are desired. In case of certain operable intrinsic lesions this method of interrupted treatment generally permits one to estimate the probable radio-sensitivity of the lesion before the second phase of the irradiation is given. In this manner the second cycle can be omitted if the lesion appears to be relatively radioresistant and one can resort to laryngectomy. The following case presents the application of the technic:

CASE 2.—A man aged 43 had experienced continuous and increasing hoarseness for one year and pain on swallowing for three months. On examination it was found that the right true and false cords were the seat of a large ulcerated mass projecting into the lumen of the larynx, with almost

7. Lederman, M., and Mill, W. A.: The Telradium Treatment of Intrinsic Cancer of the Larynx, *J. Laryng. & Otol.* 57:471, 1942.

8. In some instances an additional dose of 2,000 roentgens has been given to the opposite side about two weeks after the end of the series, as in the case reported here.

9. The dose now used is 5,700 roentgens.

10. A third cycle consisting of 2,000 roentgens in two days is sometimes added, as in the case reported here.

complete fixation of the right hemilarynx. The biopsy showed squamous carcinoma. For six days (Feb. 24 to March 1, 1941) the patient received two roentgen treatments daily with the following factors: 400 kilovolts, 5 mm. copper filter, 85 cm. distance, 5 milliamperes, ports 30 to 20 square centimeters. The doses were first day 400 roentgens, second day 500 roentgens, third day 550 roentgens, fourth day 650 roentgens, fifth day 700 roentgens and sixth day 800 roentgens, a total dose of 3,600 roentgens, measured on the skin. Roentgen intensities varied between 6.3 and 8.9 roentgens per minute. The first cycle of treatment was given over the right side of the larynx. On March 12, eleven days after completion of the first cycle, the lesion showed the first sign of regression and there was more mobility of the right hemilarynx. Two days later, the thirteenth day after the last treatment, there was noted further regression and increased mobility.

Because of this pronounced improvement, it was decided to administer the second cycle of irradiation. The interval between the two cycles was twelve days. The second cycle began on March 14 and ended on March 17, with the following factors: 400 kilovolts, filter 5 mm. of copper, 85 cm. distance, 5 milliamperes, ports 30 to 12 square centimeters. The doses were: first day 850 roentgens, second day 950 roentgens, third day 1,050 roentgens and fourth day 1,150 roentgens, with two treatments daily, a total dose of 4,000 roentgens, measured on the skin. The total dose during the second cycle was given

tissue. On Jan. 1, 1944 there was no sign of disease and the voice was normal. For some patients, especially persons with thin necks, this irradiation is somewhat too intense; hence the daily and total doses have been reduced by 10 to 20 per cent, depending on the thickness of the neck.

There are several significant features about this case. The most important is the disappearance of an extensive intrinsic squamous carcinoma of the larynx with almost complete fixation of the hemilarynx and subsequent freedom from recurrence for almost three years. Several features of the treatment are interesting. The large total dose (9,600 roentgens) administered in only twelve treatment days was possible with but little reaction in the skin and mucous membrane. The division of the treatment into three cycles with two intervals afforded an opportunity to observe the response of the lesion and plan further treatment accordingly. Finally, this case illustrates that it is practical to test the radiosensitivity of a lesion with a partial irradiation and to use the information obtained as a guide to further treatment.

3. Roentgentherapy, 400 kilovolts, eighteen consecutive treatment days, single field, diminishing port, increasing dose, total dose 6,500 roentgens: This technic is used for the more extensive so-called extrinsic carcinomas of the larynx (pyriform fossa, aryepiglottic folds, epiglottis). The following case exemplifies the method:

TABLE 5.—Results of Radiation Therapy in 170 Cases of Laryngeal Cancer (70 per Cent of Lesions Were Advanced)

Total.....	170	65	18	79	8

CASE 3.—A man aged 57 had an extensive swelling over the region of the thyroid and cricoid, obliterating the normal contour of the anterior surface of the neck. There was pronounced swelling and ulceration in the region of the right true and false cords, extending to the subglottic region. The right arytenoid was enlarged and the right hemilarynx partly fixed. There was no cervical adenopathy. Biopsy showed squamous carcinoma. Roentgen examination of the soft tissue of the larynx disclosed extensive destruction of the cricoid and thyroid cartilages. Roentgen treatment was given between July 7 and July 30, 1938 over a period of twenty-one treatment days, one treatment daily through a single right lateral field, with 400 kilovolts and 5 milliamperes filtered through 8 mm. of copper; the distance varied between 65 and 90 cm., and the size of the port varied between 8 by 10 and 3 by 4 cm. The daily dose was increased gradually from 100 to 700 roentgens, measured on the skin, and the roentgen intensity varied between 4.1 and 7.5 roentgens per minute. The total dose was 6,500 roentgens. The tumor regressed rapidly during the first few days of treatment. Approximately one week after treatment was begun, an abscess over the thyroid region was incised and evacuated. The weight increased, and the general condition improved. On October 6, about ten weeks after the completion of treatment, there was no definite evidence of disease, the general condition was excellent and the patient had no complaints. Subsequent roentgen examination of soft tissue of the larynx disclosed a remarkable restoration of the cartilages to what seems to be a normal state. There is no sign of recurrence at this time, five and one-half years after completion of treatment.

over the left side of the larynx. The first cycle was 3,600 roentgens and the second cycle 4,000 roentgens, making a total of 7,600 roentgens for the two cycles during ten days of treatment.

The maximum reaction on the skin consisted of a deep pigmentation. The maximum epithelial reaction was a mild epithelitis. The mobility of the right hemilarynx was restored to normal on April 4, eighteen days after the completion of the second cycle of irradiation. The lesion continued to regress and finally disappeared on April 25, thirty-eight days after the last treatment of the second cycle; but there remained a small, irregular, nonulcerated nodule, about 6 mm. in diameter, situated on the posterior extremity of the right true cord. On May 9, fifty-three days after the last treatment, it was decided to administer a third course of irradiation. It was not possible to decide clinically whether this nodule contained a remnant of carcinoma, and it was believed that a biopsy should not be performed. From previous experience it seemed that a third course of irradiation could be given with safety. Consequently the third course was administered in two days as follows: field over the right side of the larynx, 400 kilovolts, 5 mm. of copper, 80 cm. distance, 7.5 square centimeter port, 7.4 to 9.8 roentgens per minute, 500 roentgens twice daily for two days, or a total of 2,000 roentgens, measured on the skin. The grand total for the three cycles of irradiation was 9,600 roentgens. The last treatment was given on May 10, 1941. The nodule regressed slowly and finally resolved into a small fibrous tag about 3 mm. in diameter, which has remained stationary almost three years. It is obviously an area of scar

One must be extremely cautious in drawing conclusions from this particular case because, although the lesion was most extensive, it was obviously also highly radiosensitive.

This technic ¹¹ is the most effective so far observed for the more advanced carcinomas of the larynx. When the cervical adenopathy has been too extensive to be included in the portals, an additional cycle of treatment has been given to such areas as could not be included in the first cycle of treatment.

11. This was the first case treated by this method, and the treatment time was twenty-one days. The treatment time has now been reduced to eighteen days, and two treatments are given daily. The total dose remains the same.

RESULTS

Table 5 shows the results of radiation therapy in 170 cases of laryngeal cancer receiving adequate therapy. It should be noted that there were only 30 early lesions in the entire group. These were the movable carcinomas of the true cord. There were 20 partly fixed lesions of the true cord which may be regarded as moderately early. The remainder of the patients, numbering 120 (70 per cent) had advanced carcinoma, in many instances accompanied by cervical adenopathy. Since the table includes patients who have been free from disease only one year, no conclusion is drawn as to the permanence of the results. The table is intended only to indicate the present status of the patients.

Table 6 shows an analysis of the results of therapy for the various types of laryngeal cancer by year of admission. The variation in the percentages of patients free from disease must be due largely to corresponding differences in the proportion of advanced lesions and to some degree to the efficiency of the treatment.

Table 7 shows the results of radiation therapy in 50 cases of operable so-called intrinsic carcinomas of the true cords in which the vocal cords were freely movable or partly fixed, and table 8 shows the results in this group by year of admission.

It is instructive to analyze the failures of radiation therapy in the cases of early lesions. There were 7 failures in the 50 cases of movable and partly movable carcinomas of the true vocal cords. Two patients acquired radionecrosis as a result of a dosage that they could

* Twenty three of 28 patients, or 82 per cent, are well and have been free of disease more than three years (see table 8)

§ One died four years and seven months after treatment, of carcinoma of the palate; 1 died seven months after treatment, of angina pectoris. In both instances there was no sign of recurrence; the first is counted as cured, the second as a failure

† One died one year and eleven months after treatment, of cerebral hemorrhage; 1 died 2 years and one month after treatment, of heart disease. In both cases there was no sign of recurrence. In the table these 2 patients are counted as if they had died of cancer

disease do not tolerate the treatment well, and the presence of syphilis is especially unfavorable. Aspiration bronchopneumonia sometimes complicates the radiation therapy of advanced infected carcinoma of the larynx in old debilitated patients.

dosage. In an effort to avoid radionecrosis, inadequate treatment is usually given, with the natural consequence of low curability and high incidence of recurrence. In order to obtain the maximum benefits from radiation therapy, the intensity of the treatment must approach the tolerance of the normal tissues very closely. The individual variations in the tolerance to irradiation add to the difficulties. An important factor that lowers the tolerance of the normal tissues to irradiation is the presence of secondary infection in the larynx when treatment is begun or its entrance during the treatment. Radionecrosis can arise as a result of this complication even when the intensity of the treatment is well within the limits of safety.

One of the 7 failures was caused by radionecrosis associated with secondary infection, and in another patient with syphilis radionecrosis developed. In both the latter cases the dosage was well within the limit of safety. One patient experienced a subglottic recurrence after the disappearance of an early lesion of the true cord, and another acquired new lesions in the larynx and pharynx, probably representing lymphatic extensions. In both cases the disease showed clinical evidence of extremely high malignancy and histologic signs of severe anaplasia. One 69 year old debilitated patient refused to cooperate as regards eating and died of inanition about one month after completion of treatment.

COMMENT

Early Diagnosis.—Out of 170 cases of carcinoma of the larynx treated by adequate radiation therapy, the disease was comparatively early in only 50 cases, or 30 per cent. When one considers the entire series of 413 cases, the incidence of early lesions is approximately 20 per cent. (There were 88 comparatively early lesions in 413 cases.) Thus a reasonable chance of cure at the very outset existed in only 20 per cent of the cases. This is a challenge to the medical profession and to the public in the matter of early diagnosis and a special opportunity for leaders in cancer control. Since these lesions produce early symptoms and since most of them (lesions of the true cord) grow slowly and almost never metastasize in their early stages, the opportunity for a planned campaign of education in this field of cancer control is indeed unique.

The majority of cancers of the larynx begin on the true vocal cords. Hoarseness is an early symptom in 95 per cent of these cases. Examination of the larynx with a laryngeal mirror easily establishes the presence of a growth on the vocal cords, and biopsy readily confirms the diagnosis. Early lesions limited to one cord that have not reached the posterior commissure or crossed the anterior commissure yield about 80 per cent cures by laryngofissure and have at least an equal chance of cure by adequate radiation therapy, with restoration of the voice to normal. It is only too evident, therefore, that the problem of laryngeal cancer hinges mainly on early diagnosis. No form of internal cancer offers a more favorable opportunity for early detection. The main difficulty lies in the fact that hoarseness is such a common symptom associated with the presence of a cold. A campaign of education should be undertaken to acquaint the public with these facts, and the layman should be taught to insist on a laryngeal examination, preferably by a laryngologist, if hoarseness persists for longer than two weeks. Theoretically, a combination of early diagnosis and prompt and appropriate treatment should render cancer of the larynx largely a disease of historical interest.

Treatment.—The two most significant features in these studies are (1) the results of treatment of 50 operable carcinomas of the larynx by radiation therapy and (2) the use of a new and more effective method of irradiation. It is evident that the good results obtained in this selected group of cases are due to the fact that the lesions were comparatively early as well as to the greater effectiveness of the new method of treatment.

Of the 50 cases of operable lesions, the cords were freely movable in 30 cases and partly fixed in 20 cases. In many instances the lesion involved both true cords or extended to the false cords, ventricular cavity or subglottis. Twenty-four of the lesions, or 48 per cent, were amenable to laryngofissure. Twenty-one, or 42 per cent, were clearly too advanced for laryngofissure and would have required total laryngectomy, and in 5 cases, or 10 per cent, a decision as to the extent of the operation indicated is difficult. There were only 2 recurrences (4 per cent) in this group. Both were due to an exceptionally high degree of malignancy, indicated by the clinical course as well as by the pronounced anaplasia in the microscopic structure.

Although no positive conclusions can be drawn from the more recent cases, it was considered useful to publish the results as they stand in order that other investigators who are interested may pursue the problem along similar lines. It should be added that

although the five year period of freedom from recurrence is generally accepted as an indication of cure this figure is arbitrary. Thus it is well known that for cancer of the breast and thyroid it is entirely inadequate, whereas patients with early carcinomas limited to the true vocal cords treated by adequate radiation therapy rarely have recurrences after two years of freedom from disease. In the group of cases of movable and partly fixed carcinomas of the true cords the longest interval between treatment and recurrence was one year and seven months. This experience permits the statement that when a carcinoma of the true cord is treated by adequate radiation therapy while the cord is still freely or partly movable, the chances of recurrence or metastasis after two years of freedom from disease are extremely remote.

So uniformly unsuccessful was radiation therapy of laryngeal cancer up to 1922 that surgical operation was the only form of treatment for this disease. The situation changed in 1922, when Regaud, Coutard and Hautant¹² related their experience with roentgen therapy in 6 cases of inoperable carcinomas of the larynx before the International Congress of Otolaryngology in Paris. Coutard subsequently reported 27 per cent of five year cures among 142 cases of carcinoma of the larynx treated with x-rays in the Curie Institute of Paris. There followed numerous reports by various authors confirming these results. Harmer¹³ of London treated a series of early operable carcinomas of the true vocal cord by placing radium against the base of the lesion through a window made by resecting a portion of the thyroid cartilage, with excellent results. Further reports of radiation therapy of operable laryngeal cancer include those of Quick,¹⁴ Jackson,¹⁵ Lenz,¹⁶ Blady,¹⁷ Cutler¹⁸ and others.

Surgeons and radiotherapists alike have properly hesitated to substitute a comparatively new method of treatment for the standard surgical procedures of laryngofissure and laryngectomy. Yet there was every reason to believe that carcinomas of the larynx would yield to radiation therapy. Being epidermoid carcinomas histologically, they fall directly within the radiosensitive group in the same way as epidermoid carcinoma of the skin and mucous membrane of the mouth. The view that adult squamous carcinoma is radioresistant and hence incurable by radiation therapy has been proved a fallacy and is no longer tenable. Furthermore, a high percentage of carcinomas arising in the false cords, epiglottis, ventricular cavity, aryepiglottic folds and pyriform fossae are noticeably undifferentiated and comparatively sensitive to radiation.

In 1931 I began to treat selected cases of operable carcinoma of the true cords by means of radiation

therapy. In the beginning, this therapy was used only when the patient refused laryngectomy or when there were general contraindications to surgical intervention. As the effectiveness of irradiation increased and the results improved, my colleagues and I began to irradiate lesions of borderline operability, and finally in 1938, when the method of concentration radiotherapy seemed especially effective, we began to treat operable lesions by the new methods of irradiation by choice. It was determined early in this research that, except in isolated instances, carcinomas of the true cords with complete fixation of the larynx were unfavorable for radiotherapy. It was also established that mobility or partial mobility of the cords is a most important and favorable sign indicating relative radiosensitivity.

The progress of irradiation in the treatment of laryngeal cancer has naturally led to the question whether radiation therapy should continue to be limited to cases in which operation is contraindicated. Until recently this is the view which was held by the laryngologists. Thus Martin¹⁹ advised operation as the method of choice for intrinsic cancer of the larynx. He pointed out that some early intrinsic lesions of the cord are curable by roentgen therapy, but he added that the superiority of roentgen therapy over surgical removal has not been demonstrated. A change in this attitude began with the report of the Jacksons in 1938. Speaking from an extensive surgical experience and impressed with the improved results of roentgen therapy demonstrated by their associated roentgenologists, these authors made the following statements:

Since the year 1930, however, our observations have led us to believe that there are growths classed as operable for which the patient is justified in choosing irradiation in preference to operation. . . . Our statistics do not yet justify abandonment of the well established operation of laryngofissure when the growth is operable by this method. By operable growth in this connection we mean early intrinsic cancer of limited extent. On the other hand, when the malignant growth is locally ideal for operation but the patient is a bleeder or has a serious organic ailment such as marked arteriosclerosis, advanced cardiac disease, intractable diabetes, pulmonary tuberculosis, a psychosis or any other condition abnormally shortening life expectancy, we would now class the patient as unsuitable for operation. Classification of patients has been somewhat changed by the improved results obtainable by irradiation and we now classify as unsuitable for operation a somewhat larger proportion of patients with early intrinsic disease. . . . As between a laryngectomy and irradiation, we are decreasing the number of laryngectomies in proportion to the number of patients treated with irradiation.

The authors concluded that their experience warranted them in the belief that the future will probably see a progressive decrease in the relative number of laryngectomies.

The trend is further indicated by Schall,²⁰ who stated recently that "the ideal treatment is one that not only eradicates the disease but also leaves a normal physiological state. External irradiation answers these requirements. Laryngeal cancer that responds to irradiation leaves the patient with a normal, or nearly normal, useful voice." For localized lesions of the cord, Schall advises irradiation if the cancer is of grade 3 or 4 (Broders' classification) and laryngofissure for grades 1 or 2.

Examination of table 8 shows that 28 patients were treated in the years 1938, 1939 and 1940 and that 23, or 82 per cent, are alive and have been free from disease more than three years. The Jacksons²¹ cited between 80 and 85 per cent of three year results in patients treated by laryngofissure in strictly suitable cases. Of the 28 lesions in this series, only 14 were early enough for laryngofissure, 10 would have required total laryngectomy, and for the remaining 4 the decision is difficult. It seems, therefore, that the results of radiation therapy as administered in this series of cases are superior to those of surgery, especially when one considers that at least 10 patients who would have required total laryngectomy were rendered free from disease by radiation therapy, with restoration of the voice to a practically normal state.

For surgeons who may choose laryngofissure in preference to radiation therapy, these results should lead to a more strict selection of cases for laryngofissure. In any event, patients who are not strictly suitable or are definitely unsuitable for laryngofissure but whose lesions are not completely fixed should be given an opportunity to choose radiation therapy in preference to total laryngectomy.

The procedure at this time is to perform laryngectomy for fixed intrinsic lesions in which there are no general contraindications to operation, and as the results of irradiation improve we are more strict in our classification of operability; but we go one step further, which we consider our results justify. When the cords are still movable or partly movable, we choose irradiation in preference to surgical operation regardless of the histologic grading. Some of these lesions are so early as to be amenable to laryngofissure; others would require complete laryngectomy. Table 6 shows the results obtained with 20 fixed lesions of the true cords in patients who either refused operation or in whom there were general contraindications to laryngectomy. Only 4 patients are free from disease. In cases in which a decision between surgical operation and irradiation is difficult for local or general reasons, we apply the radiotherapeutic test and are guided by the response to the initial cycle of treatment. Included in this group are patients whose lesions are too extensive for laryngofissure and to whom loss of the voice is a matter of special concern. Under these circumstances we sometimes feel justified in executing either a partial or complete irradiation with the understanding that a laryngectomy will be performed if the irradiation fails. In some instances we have had to resort to operation, and in others the patients are apparently cured by irradiation. The selection of treatment is highly individual, and no rigid rule can be applied to all cases. The method of treatment depends on numerous factors, including the location and extent of the lesion, the extent of infiltration as indicated by mobility of the structures, the general condition of the patient and in certain instances the patient's ability to adjust himself to laryngectomy.

CONCLUSIONS

Intrinsic squamous carcinoma of the larynx is curable by correct radiation therapy, the percentage of cures depending on the extent of the lesion and the efficiency of the treatment. Concentration radiotherapy has

proved to be the most effective form of irradiation. When the cords are freely movable or only partly fixed, the curability is high; but when they are completely fixed, cure is difficult and rarely accomplished. Eighty-two per cent of the patients with movable and partly fixed lesions of the true cords are alive and have been free from disease more than three years. The voices of these patients are practically normal. The most significant result of this research is the eradication by means of an improved method of radiotherapy of a group of intrinsic squamous carcinomas of the larynx so advanced as to have required total laryngectomy and hitherto generally regarded as radioresistant and incurable by irradiation.

LIEUTENANT EUGENE L. LOZNER
MEDICAL CORPS, UNITED STATES NAVAL RESERVE
AND

COMMANDER JOSHUA M. DEEVER
MEDICAL CORPS, UNITED STATES NAVAL RESERVE

The importance of skin grafting in military reconstructive surgery cannot be overestimated. Improvements in technic of grafting must be sought for constantly and particularly improvements which will shorten operative time and increase percentage of takes. The possibility of such an improvement using thrombin and fibrinogen arose from the observations of Dr. M. E. Sano of Temple University School of Medicine, who used heparinized plasma and pressure as an adhesive for grafts.¹

Thrombin and fibrinogen have both been known for many years, as has the reaction between them, namely the capacity of the former to transform the latter into insoluble fibrin. It is said to be this reaction which is responsible for blood coagulation. A main deterrent to the exploration of the medical and surgical potentialities of these materials had been the difficulty and expensiveness of their preparation. This has been circumvented in recent years by the work of Seegers² and Parfentjev³ and by the improvements in fractionation

of human plasma by E. J. Cohn and his associates.⁴ In the latter fractionation both thrombin and fibrinogen become by-products of human serum albumin. The extensive use of the latter by the armed forces as an "antishock" agent has increased the availability of these by-products. Thrombin has already been mentioned several times in the literature as a local hemostatic.⁵ Fibrinogen has recently been employed in neurosurgical and tendon repair work with encouraging results.⁶ To our knowledge neither of these materials has been used in connection with skin grafting except perhaps the use of thrombin as an adjunct to hemostasis. It is our purpose in this paper to present findings on 8 patients skin grafted with varying technics using thrombin and fibrinogen.

Because it is well known that results in skin grafting are difficult to evaluate unless one standardizes all conditions, an outline of the general and local treatment will be presented first. Before the start of these observations, it had been confirmed by two of us⁷ that unsatisfactory results occurred in the taking of grafts unless hemoglobin, plasma proteins, prothrombin and the general condition of the patient were kept at a high level. Accordingly, these practices were put into effect in the course of the use of thrombin and fibrinogen:

GENERAL TREATMENT BEFORE AND AFTER GRAFTING

1. High protein (more than 100 Gm. daily), high carbohydrate, high cysteine, low fat diet.
2. Supplementary routine vitamin A, thiamine, nicotinamide, riboflavin, ascorbic acid and B complex in doses exceeding daily requirements. Vitamin K as necessary to maintain normal prothrombin level.
3. Ferrous sulfate and blood transfusions as necessary to maintain hemoglobin above 13 Gm. per hundred cubic centimeters.
4. Plasma and blood transfusions as necessary to maintain plasma proteins above 6.5 Gm. per hundred cubic centimeters.

LOCAL TREATMENT OF BURNS PRIOR TO SKIN GRAFTING

1. Six per cent sulfanilamide ointment, pressure dressings and splints as described elsewhere.⁸
2. Change of dressings after ten to fifteen days and subsequent open treatment with saline and chloroazodin compresses, sulfanilamide 10 per cent calcium carbonate powder,⁹ petrolatum gauze and adhesive strapping or reapplication of 6 per cent sulfanilamide ointment and pressure.
3. During the forty-eight hours before grafting, continuous chloroazodin compresses and sulfanilamide powder.

This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the United States Navy. The opinions and views set forth in this article are those of the writers and are not to be considered as reflecting the policies of the Navy Department.

The products of human plasma fractionation employed in this work were prepared from blood collected by the American Red Cross and processed by the Department of Physical Chemistry, Harvard Medical School, Boston, under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and Harvard University.

Most of the thrombin used in this work has been the rabbit "hemostatic globulin" supplied by the Lederle Laboratories, Inc. A smaller amount of the thrombin and all the fibrinogen used was human in species and supplied by Drs. S. H. Armstrong and E. J. Cohn of the Department of Physical Chemistry, Harvard Medical School. Some of the latter was redissolved, redispensed into smaller containers, refrozen and redried by the Blood Plasma Laboratory of the U. S. Naval Medical School.

TECHNIC OF SKIN GRAFTING USING THROMBIN
AND FIBRINOGEN

On the basis of the experience to date, the following technic has been evolved:

1. Thrombin is supplied dried in vials requiring 5 cc. of distilled water for regeneration.
2. Fibrinogen is supplied similarly.
3. Thrombin is applied as a spray by means of an atomizer.
4. Fibrinogen is applied by dipping the grafts or flooding the surface.
5. The grafts are cut. Free hand, simple pinch or split thickness grafts taken by the Padgett dermatome were used. All split thickness grafts were perforated to allow for drainage.
6. Bleeding from the donor site is controlled with thrombin, dusted with sulfanilamide 10 per cent calcium carbonate powder and a 6 per cent sulfanilamide ointment dressing applied.
7. The recipient site is cleansed with ether; exuberant granulations and undesirable scar tissue are removed by sharp dissection, and bleeding is controlled by thrombin, pressure and elevation.
8. The grafts are dipped in the fibrinogen solution and fitted on the site to conform to the defect. The area is then sprayed with thrombin and simultaneously flooded with fibrinogen and the pressure dressing applied immediately.
9. When large grafts are sutured into place, fibrinogen and thrombin are run under the graft following the suturing, and immediately pressure is applied for two minutes with a rubber sponge.
10. The application of hot packs to the grafts was found to increase the adhesiveness still further.

DRESSING APPLIED TO ALL GRAFTS

1. Perforated cellophane is applied over the graft and sprayed with sulfanilamide 10 per cent calcium carbonate powder.
2. Over the cellophane are placed ten layers of gauze saturated with glycerin¹⁰ containing 2 per cent of sulfanilamide. A sheet of plain cellophane is placed over this and then rubber sponges or pads of cellucotton that are secured by adhesive tape or adhesive so as to maintain continuous firm pressure.
3. Grafts are dressed on the third, fifth and seventh days and from then on as indicated.

REPORT OF CASES

CASE 1.—On June 1, 1943 bad burns were sustained over the face, hands and forearms and feet. All areas healed quickly except the backs of the hands and the fingers, which had third degree burns. On June 28 the hands were ready for grafting, and split thickness grafts were applied by the collodion technic of Poth¹⁰ and a few sutures. Only portions of the grafts took because of uncontrollable hemorrhage that formed clots under the grafts, and because of the inflexibility of the collodion. On July 4 the left hand was grafted with poor results, apparently from hemorrhage under the grafts and slipping due to poor bandaging. The areas became infected, and it was impossible to graft again until August 2. At this time the split thickness grafts were cut into 1 cm. or smaller squares¹⁰ for use as pinch grafts. It was difficult to get these to adhere to slanting surfaces or in the webs of the fingers. It took a variable period for the pieces to stick without

any additional procedures. It was decided at this time to compare whole blood, plasma, pooled plasma and fibrinogen solution with and without thrombin with respect to speed and efficacy of adherence of the grafts.

The granulating area was painted with the blood, plasma and fibrinogen and then the pieces of grafts were dipped in the thrombin solution and applied to the painted recipient areas and the time was measured until the grafts no longer would slide when held perpendicularly and until one could demonstrate fibrin strands by teasing the edge of the graft with a needle. The results are presented in the accompanying table.

The thrombin was most effective in controlling hemorrhage from granulating surfaces after trimming and from the donor sites. All these grafts took except a very few placed in the webs of the fingers and over the joints, and this was probably due to inadequate immobilization.

CASE 2.—Both legs were extensively burned about seven days before entry. Infection set in. After entry to the hospital both limbs were immobilized in plaster casts after application of 6 per cent sulfanilamide ointment. After two weeks the casts were removed. The left leg was completely healed. The right leg presented a large, irregular, clean granulating surface involving the side of the ankle, extending up to the head of the fibula and from the anterior border of the tibia to the midpart of the calf posteriorly. No epithelial islands remained

Comparative Study of Various Agents Applied Between Graft and Recipient Area in Case 1

Materials Applied Between Graft and Recipient Area	Time to Adhere, Minutes	Degree of Adhesiveness	Comment
Nothing (control).....	3-13	Low	
Whole citrated blood.....	4-7	High	Vision obscured by clotted blood
Whole citrated blood plus thrombin	3-1½	High	Vision obscured by clotted blood
Patient's citrated plasma.....	3-5	High	
Patient's citrated plasma plus thrombin	3-1½	High	
Pooled citrated plasma.....	5-7	High	
Pooled citrated plasma plus thrombin	¼-5/12	High	
Fibrinogen.....	2-8	High	
Fibrinogen plus thrombin.....	¼-¾	High	

within this area, but epithelial proliferation was going on actively from the surrounding skin edges. Split thickness grafts were taken from the thighs, fitted to the granulating area and held in place with a few stay sutures. There was considerable bleeding around the sutures. Thrombin, elevation and pressure quickly controlled this hemorrhage. The thrombin solution was then run under the grafts, followed by fibrinogen solution and pressure; within one minute the graft was held firmly against the granulations. The usual dressings were applied, and the leg was placed in a posterior plaster splint.

Hemorrhage from the two donor sites was controlled within one minute by thrombin and pressure.

About 40 per cent of the graft slipped anteriorly and did not take. We believe this was due to too much tension on the sutures and could have been avoided by letting the graft retract maximally before suturing. The remainder of the graft did well, and further grafting was not necessary.

CASE 3.—A traumatic amputation of the tip of the third left finger was treated with saline solution and chloroazodin compresses and within one week was ready for grafting. The skin edges and exuberant granulations were trimmed. Considerable bleeding started that was not controlled by elevation but was stopped within two minutes by thrombin, pressure and elevation. Then multiple pinch grafts were applied. It was very difficult to apply a dressing without brushing off the grafts; therefore the grafted area was flooded with fibrinogen solution, and thrombin was sprayed onto it with an atomizer. Within a few seconds a thin fibrin gel was anchoring the pinch grafts in place, and this greatly facilitated the application of the dressing. All the grafts took, and within two weeks the patient had a usable finger.

10. Poth, E. J.: A Technic of Skin Grafting, Surg., Gynec. & Obst. 75: 779-784 (Dec.) 1942.

CASE 4.—A broken ankle and a contused, lacerated left thigh resulted in a large granulating surface measuring about 5 inches by 3 inches.

A split thickness graft was applied and sutured loosely in four places. Citrated plasma, obtained from the patient, was run under the graft followed by rabbit thrombin. There was firm adherence within one and a half minutes. Serum formed under the upper half of the graft, and this part did not take. We believe this was due to an inadequate pressure dressing.

The upper half was regrafted with pieces of free hand grafts about 1 inch square after being dipped in the patient's plasma and sprinkled with human powdered thrombin. These grafts took completely.

CASE 5.—A contused, lacerated injury was sustained to the anterior surface of the leg just lateral to the tibia. This resulted in an elliptic granulating wound 6 inches long and $2\frac{1}{2}$ inches wide. A split thickness graft was very loosely sutured into place after the surface of the granulations had been dusted with powdered human thrombin. The hemorrhage from the sutures was easily controlled by thrombin and pressure. The blood that flowed under the graft was clotted, and the graft was snugly held in place against the granulations. This graft took completely.

Hemorrhage from the donor area was controlled almost entirely by powdered thrombin that was rubbed on the surface, except for one small artery that persisted in spurting.

CASE 6.—Gas gangrene had developed in comminuted, compound fractures of the toes and metatarsals. All the toes except the small toe were amputated (guillotine type) at the head of the metatarsals. Free incision of the skin over the foot was performed. With sulfadiazine, local hydrogen peroxide and zinc peroxide and polyvalent antitoxin the patient recovered. A large irregular granulating defect over the heads of the metatarsals resulted, measuring $3\frac{1}{4}$ by $1\frac{3}{4}$ inches. This was covered with a split thickness graft that was sutured in place with interrupted sutures. Considerable bleeding started and was controlled by thrombin and pressure except at the plantar border of the graft, where all measures were useless. The usual pressure dressing was applied, but a hematoma developed under the plantar half of the graft and this area did not take.

Later, pinch grafts were applied to this area and flooded with fibrinogen and thrombin solutions. These grafts took completely.

A large hematoma then developed under the thin epithelium that had grown in from the surrounding skin and had not been excised at the time of grafting. This was excised, cleaned up and grafted. This time a small piece of split thickness was taken, cut into small squares (1 cm. or less) and placed on the raw surface and secured by the fibrinogen-thrombin technic. The immediate result was excellent. There was less than a millimeter between the individual pieces. No suturing was necessary, and less time was consumed than if one had sutured a single piece in place.

This patient is still under observation.

CASE 7.—Extensive damage to both thighs had left a granulating defect $4\frac{1}{2}$ by 6 inches on the right thigh and $2\frac{1}{4}$ by $3\frac{3}{4}$ inches on the left thigh. Both surfaces were very concave. Split thickness grafts were taken, and hemorrhage from the donor sites was dramatically controlled by thrombin within forty-five seconds.

On the right leg half inch squares of skin and irregular odd shaped pieces were fitted together after flooding the granulations with the patient's own citrated plasma. Each piece of skin was dipped in liquid thrombin (rabbit). After two minutes the grafts were firmly adherent. On the left leg one perforated piece of skin was sutured in place, and then thrombin and plasma were run under the graft and pressure was applied. After two minutes the graft remained firmly adherent to the concave depression. The two sides did equally well with complete takes.

CASE 8.—A burned heel resulted in a $1\frac{1}{2}$ inch round defect. This was covered with multiple pinch grafts, flooded with fibrinogen solution and sprayed with rabbit thrombin. Imme-

diately a firm fibrin gel formed which held all the grafts in place. The usual dressing was applied. The result was a complete take and a valuable, usable heel resulted.

COMMENT

Poth¹⁰ has pointed out four factors with respect to skin grafting which "militate against early vascularization: (1) an anatomically poor recipient bed, (2) faulty approximation of graft and recipient surface, (3) an improperly prepared graft and (4) the presence of infection." The evidence that has been presented on the use of thrombin and fibrinogen appears to indicate that these agents may be of distinct value with regard to the first two of these factors. By the utilization of thrombin it is possible to trim granulations and scar tissue until the bed is automatically perfect and yet control the hemorrhage in the bulk of instances very quickly. A more extensive report on our use of thrombin as a hemostatic will appear elsewhere.¹¹

Approximation of graft and recipient bed is enhanced by the combined use of thrombin and fibrinogen. The first stage of the taking of a graft is consummated almost instantaneously by the formation of a thin fibrin cement between the graft and recipient area, into which vascular beds may grow under ideal conditions. Dead space can be obliterated completely. Here it should be pointed out that, by the use of relatively pure fibrinogen instead of fresh plasma as its source, serum formation is minimized. The latter phenomenon occurred in case 4 and delayed the take.

Among the advantages in this technic we were impressed perhaps most of all by the amount of time saved. Hemorrhage was controlled quickly. Fewer sutures were used and at times none at all. Dressing was simplified because of the greater adherence of the grafts. The application of grafts in awkward places such as the webs of the fingers where suturing was difficult was simplified by the omission of suturing.

SUMMARY AND CONCLUSIONS

1. Thrombin and fibrinogen have been used in skin grafting.

2. Hemorrhage from the recipient and donor sites was quickly and easily controlled by thrombin in the majority of instances.

3. The grafts were quickly and well anchored into place by the combined use of thrombin and fibrinogen, so that fewer sutures or at times none at all were necessary.

4. It is believed that the use of thrombin and fibrinogen will be a valuable adjunct to skin grafting. It will not replace suturing completely. It is particularly useful with pinch grafts and flagstone grafts.

Time Lost Because of Illness.—The time lost because of illness averages between seven and nine days per employed person and represents about 3 per cent of the usual working year. It is estimated that the 36 million wage earners in the country lose about 250 million work days and the 24 million school children lose about 175 million days in school each year from illness. The financial loss of the country as a whole represented by the lost earning power and reduced production totals well over 2 billion dollars a year, equivalent to one-half the cost of maintaining the national government.—The Hospital in Modern Society, edited by Arthur C. Bachmeyer and Gerhard Hartman, New York, Commonwealth Fund, 1943.

Clinical Notes, Suggestions and New Instruments

GENERALIZED EXFOLIATIVE DERMATITIS DUE TO SULFADIAZINE

ROSWELL D. JOHNSON, M.D., NEW HAVEN, CONN.

The object of this case report is to present one of the most alarming toxic reactions of sulfadiazine therapy—generalized exfoliative dermatitis—together with a description of the treatment employed.

REPORT OF CASE

W. A., a boy aged 10 years of Scandinavian parentage, whose history included a Rammstedt procedure for hypertrophic pyloric stenosis at the age of 6 weeks, two convulsions associated with the onset of acute infections at the ages of 1½ years and 3½ years, streptococcal fever with suppurative cervical adenitis at the age of 3½ years and the usual acute exanthems of childhood, had never been treated with any sulfonamide drug in any form previous to the onset of the present illness, nor had he ever had a dermatitis from any cause.

The family history was completely negative in all respects save for asthma, which developed late in the life of the maternal grandmother.

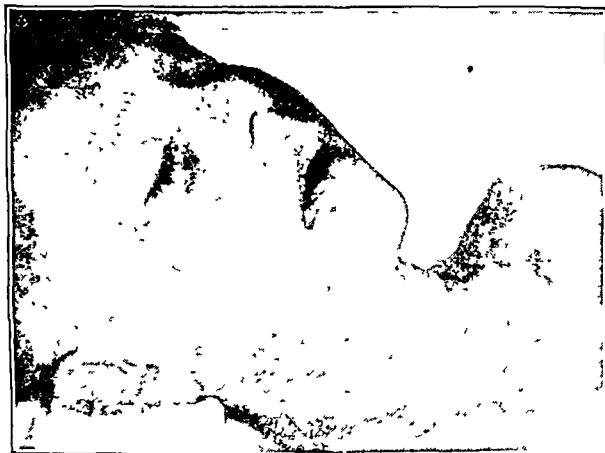

Fig. 1.—Appearance of patient just before height of exfoliative dermatitis. Note here the acute illness of the patient, the eyes swollen shut and crusted blood on the lips.

The present illness started about July 13, 1943 with an acute respiratory infection. The temperature gradually rose to 40 C. (104 F.) on July 16 and the family physician made a diagnosis of pneumonia of the left lower lobe. Bacteriologic or x-ray studies were not done. The patient remained at home, and sulfadiazine therapy was started that day. As an initial dose the child was given 1.5 Gm. by mouth followed by 0.5 Gm. four times daily. The patient's weight was 35 Kg. (77 pounds). The temperature slowly fell to normal within the course of a week. On the eighth day of treatment the drug dose was cut to 1.5 Gm. daily. On the ninth day the temperature was 38.4 C. (101.1 F.) and the face was noted to be very red. On July 25 (tenth day) the drug was stopped, the temperature was still 38.4 C. and the facial redness still pronounced. The following day the mother noted a "prickly heat" rash on the boy's face and arms and a temperature of 39.2 C. (102.5 F.). Almost overnight the rash became much worse, myriads of vesicles appeared and he was admitted to the pediatric service of the New Haven Hospital on July 27.

On admission the temperature was 40.4 C. (104.7 F.); the boy was rational but acutely and seriously ill. A definite morbilliform rash covered the entire body, confluent in areas. Over

the neck, shoulders and arms were numerous large blebs, some of which had already ruptured (figs. 1 and 2). No jaundice was present. There was a very severe conjunctivitis with purulent discharge, chemosis and photophobia. An ulcerative bleeding gingivostomatitis was present with crusted blood on the lips. The cervical nodes were moderately enlarged and very tender.

Fig. 2.—Local condition of skin. Note the large bleb and many smaller ones with complete involvement of entire surface.

The lungs and heart were essentially normal. There was considerable edema of the glans penis and some mucosal pouting at the meatus. Voiding was both difficult and painful. It was impossible for the boy to take any significant amount of fluid by mouth; proctoclyses were impossible, for even the minor trauma of inserting a thermometer initiated rectal bleeding.

Fig. 3.—Appearance of patient two months after recovery, showing normal skin.

Because of the close resemblance between the skin of the patient and that seen in a severe scald, it seemed logical to treat him as for a burn. Consequently, the skin was gently wiped with alcohol, sterile petrolatum strips were applied and overlaid with gauze packs and fluffs, and an elastic bandage then wound snugly over all. This completely covered the extremities and

most of the torso. It was left in place for nine days. Pain was controlled with morphine and particular attention paid to care of the mouth, a topical anesthetic being used at times to ease the discomfort and aid in taking fluids by mouth. Supportive treatment included a constant intravenous drip of 2,500 cc. of fluid daily consisting of 10 per cent dextrose 2 parts and isotonic solution of sodium chloride 1 part. To this was added 100 mg. of ascorbic acid, 10 mg. of thiamine and 25 mg. of niacin, a total of 1,100 cc. of pooled plasma and 6.25 cc. of fresh whole citrated blood.

On the second hospital day the boy vomited a piece of tissue measuring approximately 10 by 0.8 by 0.2 cm., presumably an esophageal cast, judging from the mucosal folds present. On the fifth hospital day the patient reached his lowest point, and recovery seemed improbable. New blebs were appearing daily and continued to do so until the eighth day. A progressive granulocytopenia was present for a time with a very definite shift to the left and the non-segmented forms greatly outnumbering the segmented neutrophils. Ten units of crude liver extract was given intramuscularly in divided doses with equivocal effect. At no time were the blood platelets or the bleeding time essentially altered. By the ninth hospital day the boy was noticeably better, and improvement thereafter was steady. He was discharged from the hospital on the twentieth day with new skin

Clinical Course

Date	Sulfadiazine Levels		White Blood Cells	Non-seg./Seg.	Plasma Protein	Blood Culture	Blood	Plasma
	Blood	Vesicles						
7/27	1.0	2.1	10,300	35/60	..	Negative	..	250
7/28	11,100	31/56	8.0 G.	Negative
7/29	13,100	36/54
7/30	6,200	37/63	7.1	B. subtilis	250	200
7/31	4,850	37/22	...	Negative
8/1	4,700	24/12	6.8	...	375	300
8/2	4,000	23/9	6.5	B. subtilis	...	250
8/3	7,150	19/8	150
8/4	0.0	1.0	8,400	16/8
8/5	Negative
8/6	12,400	24/48
8/8	10,500	22/52

over the blistered areas and the mucous membranes greatly improved. Follow-up examinations one week after hospitalization and two months later showed complete recovery (fig. 3).

Details of the clinical course are presented in tabular form.

Nine examinations of urine during the period showed absence of proteinuria, hematuria and casts. The urinary output was usually 1,000 to 1,500 cc. daily.

On August 2, blood electrolyte studies revealed chlorides 96.4 milliequivalents per liter, sodium 134.5 milliequivalents per liter and potassium 5.6 milliequivalents per liter. The non-protein nitrogen was 25 mg. per hundred cubic centimeters. Repeated cultures of blebs were sterile. No virus studies were done.

COMMENT

This additional case of severe exfoliative dermatitis due to sulfadiazine is probably one of the most extensive reported with recovery.¹ There was nothing about the dosage of the drug that was unusual; the daily dose of 2 Gm. (0.85 grain per pound) is well within the accepted range of safety, and the total dose of 19.5 Gm. is frequently exceeded without toxicity.

The plan of therapy, particularly that concerning the local care of the skin, was designed to prevent infection, minimize protein loss and simplify nursing procedures with the patient.

A CASE OF SILICOSIS CAUSED BY WHEAT DUST

THOMAS F. HEATLEY, M.D.; DALTON KAHN, M.D., AND
C. R. REX, M.D., TOLEDO, OHIO

F. B., a man aged 55, presented himself for examination on March 4, 1941 with a complaint of severe dyspnea on exertion, dry cough and pain in the chest. His history showed that he

Fig. 1.—Appearance March 4, 1941.

that he could see only a few feet before him. He kept this up for eight years, from 1929 to 1937, when he was obliged to quit because of progressive shortness of breath. He had no history of pneumonia or tuberculosis.

Examination (T. F. H.) showed that he was moderately well nourished and above average intelligence. Blood pressure was 90 systolic, 70 diastolic. Examination of the urine showed no pathologic condition of the kidneys. There was no evidence of syphilis or of tuberculosis. Respirations were increased, 26 per minute, and the chest expansion manifestly diminished.

The stereoscopic examination of the chest (D. K.) revealed that the thorax was barrel shaped and symmetrical. The right base showed no evidence of fluid, and the dome of the diaphragm was smooth and showed no adhesions, the bronchial tree markings were accentuated and showed fibrosis, the hilus glands showed increased density with advanced fibrosis, the bronchial tree markings were accentuated and extended well toward the periphery in the axillary space, the upper lobe markings were accentuated and the apex was not entirely clear or well aerated.

The left base was clear and the diaphragm dome was smooth; the cardio-phrenic angle was not as sharp as normal. The hilus glands were increased and showed definite fibrosis with but little evidence of calcification. Definite mottling extended from the hilus into the parenchyma of the lung; both upper and lower lobes were involved. The heart shadow was almost entirely on the left, and the aortic knob was normal. The apex was clear and showed good aeration.

The radiologic diagnosis was chronic pneumoconiosis involving both lungs but more definite on the right side. No demonstrable evidence was obtained of tuberculosis or cavitation.

Samples of dust were gathered from one of the cars while it was being loaded with wheat and from the aforementioned

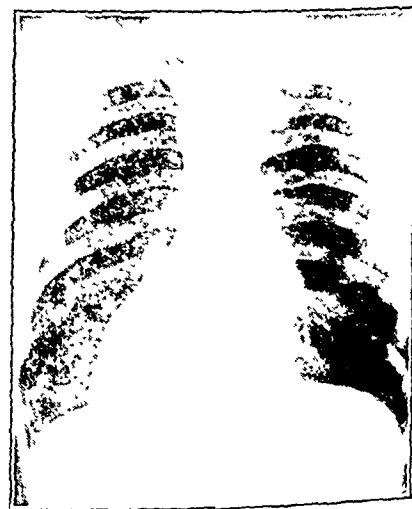

Fig. 2.—Appearance Oct. 18, 1943.

tunnel with the belt conveying wheat, and these were examined chemically and microscopically by one of us (C. R. R.).

The material under examination was found to be composed of whole wheat grains, oat hulls and particles of broken grain. Other particles in the form of finer particles under screen separation were found in the percentages given in table 1.

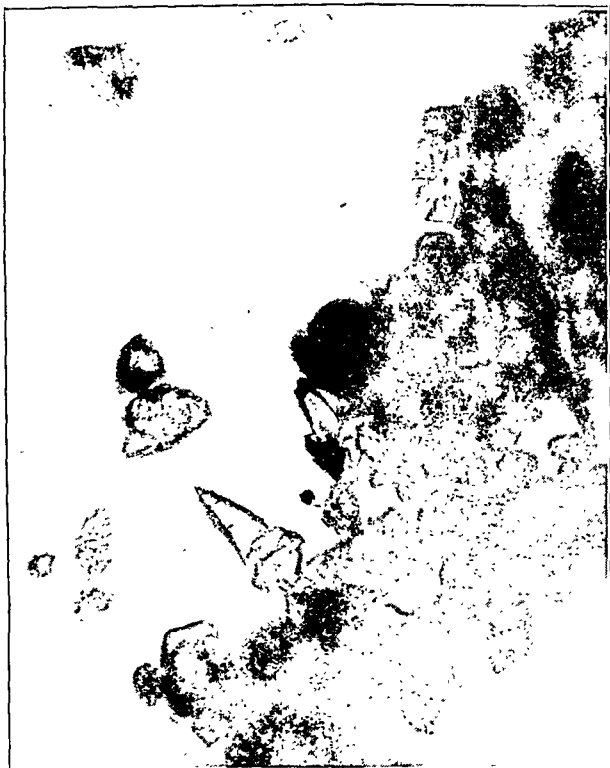

Fig. 3.—Silica from car found passing 325 mesh sieve; $\times 1,000$.

The results of the tests on the dust from the car are given in table 2. The dust from the tunnel was of much the same character but contained a larger percentage of very small particles, no less than 31.55 per cent passing through the 325 (0.044 mm.) mesh; i. e., 31.55 per cent were less than 44 microns in size. The silica content of this dust was 9.96 per cent. In

TABLE 1.—Percentages of Particles

	In Millimeters	Percentage
100 mesh.....	0.147	8.7
150 mesh.....	0.104	4.0
200 mesh.....	0.074	4.0
325 mesh.....	0.044	2.0
Passing 325 mesh.....	0.044	20.24
4.0% between 147 microns and 104 microns		
4.0% between 104 microns and 74 microns		
2.0% between 74 microns and 44 microns		
20.5% from 1 to 44 microns		

both samples the proportion of free silica in the dust rose as the size of the particles fell. It was also observed that the smaller particles were more irregular in shape and had sharper edges than the larger ones.

A second examination was made on Oct. 15, 1943. Comparison of the x-ray films with those of 1941 showed that, without any further exposure to silica-containing dust, the disease had progressed. At neither examination was there any evidence of tuberculosis.

The hilus regions of both lungs showed an increase in density of the fibrous tissue; the lung markings generally showed a hardness compared with former plates. The emphysema was

more pronounced and the heart shadow contour had changed as a result of the changed lung condition.

It was our opinion that the vital capacity of the lungs had been diminished and this patient's emphysema was progressing because of silicotic deposits in the lung tissue.

SUMMARY

A workman employed for eight years in an atmosphere thick with dust from wheat (loading and unloading railway cars) presented a roentgenogram typical of advanced silicosis without evidence of tuberculosis.

		19.96%

Examination of the dust gathered at his working places showed that 20.25 and 31.55 per cent of the particles were between 1 and 44 microns in size. The silica content of these particles was 19.96 and 9.96 per cent.

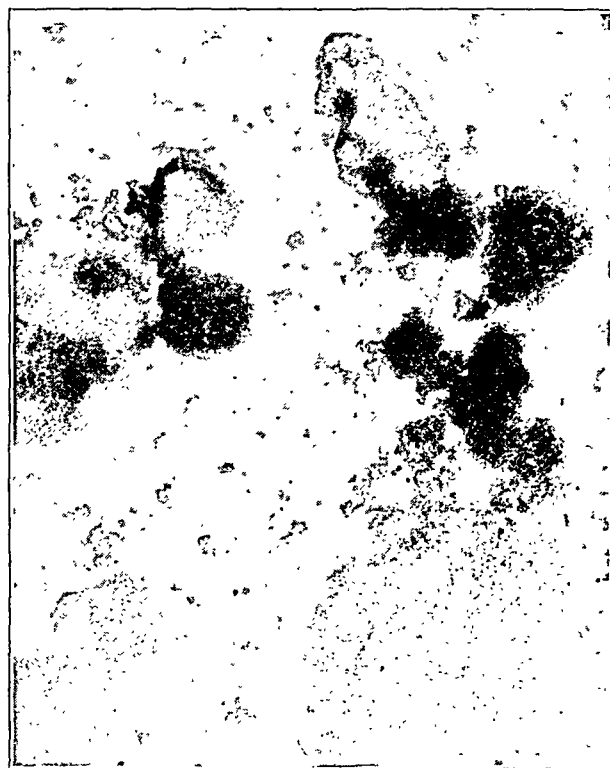

Fig. 4.—Silica from tunnel found passing 325 mesh sieve; $\times 1,000$.

A second examination, made two years later, showed that the fibrotic process in the lungs had progressed, although there had been no further exposure to silica-containing dust.

At present, Jan. 11, 1944, he is completely incapacitated.
1838 Parkwood Avenue.

Special Article**A CLINICAL EVALUATION OF VACCINATION AGAINST INFLUENZA****PRELIMINARY REPORT**

By MEMBERS OF THE COMMISSION ON INFLUENZA, BOARD FOR THE INVESTIGATION AND CONTROL OF INFLUENZA AND OTHER EPIDEMIC DISEASES IN THE ARMY, PREVENTIVE MEDICINE SERVICE, OFFICE OF THE SURGEON GENERAL, UNITED STATES ARMY

In the autumn of 1943 members of the Commission on Influenza, and associates, Board for the Investigation and Control of Influenza and other Epidemic Diseases in the Army, Preventive Medicine Service, Surgeon General's Office, United States Army, undertook with Dr. Thomas Francis Jr., as director, to carry out a controlled clinical trial of the prophylactic efficacy against epidemic influenza of a concentrated, inactivated vaccine containing the viruses of influenza types A and B. Preceding studies had shown that a vaccine similarly prepared was capable of furnishing definite

ately ten times in isotonic solution of sodium chloride following adsorption to, and elution from, the embryonic erythrocytes.² The infectious capacity was inactivated by solution of formaldehyde in a concentration of 1:5,000. Phenyl mercuric nitrate 1:100,000, or borate 1:50,000, was then added for bacteriostatic purposes. The material was bottled in 50 cc. amounts in liquid form. The standard requirements for sterility of bulk and bottled biologic products were met.

Each 1.0 cc. of the vaccine was made up of 0.5 cc. representing type A virus recovered from 5.0 cc. of allantoic fluid and 0.5 cc. representing the type B virus recovered from 5.0 cc. of allantoic fluid. The type A component represented equal parts of the PR8 strain and of the Weiss strain, isolated in May 1943.³ The type B component contained only the Lee strain.

The vaccine was tested by inoculation of mice and eggs to demonstrate that no infectious capacity remained. Its capacities to agglutinate chicken erythrocytes⁴ and to induce immunity in mice after intraperitoneal inoculation were also determined as indicative of antigenic activity.

Control material consisting of isotonic solution of sodium chloride to which solution of formaldehyde

* The incidence 11/23 to 12/6/43 is based to a large extent on questioning, since unit was on furlough during this period.

† These data are considered incomplete. The low incidence is probably related to the difficulty encountered in obtaining proper reporting among the high percentage of men living in private homes.

protection against experimental induction of influenza A or B.¹ The present account constitutes a preliminary clinical evaluation of the influence of vaccination on the incidence of influenza during the epidemic of influenza A which occurred in November and December 1943.

VACCINE

The vaccine was prepared in the laboratories of biologic firms according to specifications furnished by the commission and purchased at minimal cost with commission funds. Virus was obtained from the allantoic fluid of embryonated hen's eggs inoculated forty-eight hours earlier. The virus was concentrated approxi-

1:5,000 and phenyl mercuric nitrate 1:100,000 were added was prepared, bottled and subjected to the same tests for sterility.

THE PLAN OF STUDY

With approval of appropriate authorities, the study was carried out in Army Specialized Training Program units of eight universities in different parts of the United States and in a ninth group comprising the members of Army Specialized Training Program units of five New York medical and dental colleges. Approximately 12,500 men were involved. The populations were highly stable, so that the proportion of men lost from the study was extremely low. In most instances the men were housed as large groups in dormitories.

Vaccine prepared by two different firms was employed in all locations. Except in one unit equal volumes of the two preparations were mixed just before inoculation, so that no selection occurred on this basis. Each

Support and assistance in arranging the studies were furnished by Col. Charles M. Watson, Col. Don C. Hildrup, Col. Herbert C. Gibner and Col. Howard C. Moore, respectively, surgeons of the 2d, 6th, 7th and 9th service commands.

Continued aid and cooperation were furnished by the commanding officers of the different A. S. T. P. units among which the investigations were made, namely Col. Edwin R. Van Deusen, Cornell University; Col. Arthur E. Fox, Princeton University; Lieut. Col. J. D. Cope, Rutgers University; Col. Raymond P. Cook, C. C. N. Y.; Col. Frederick C. Rogers, University of Michigan; Col. Harry King, University of Minnesota; Col. Luke D. Zech, University of Iowa; Col. Francis R. Hunter, Iowa; Col. Luke D. Zech, University of Iowa; Col. William, Columbia University of California; Lieut. Col. Phillip B. Connelly, Cornell Medical College; Capt. Robert Geiss, Long Island Medical College; Major Albert C. Dorat, New York Medical College, and Capt. George F. Dyson, New York University College of Medicine and Dentistry.

company or organization within a unit was divided in half, so that alternate individuals received, respectively, vaccine and control material. One dose of 1.0 cc. was given subcutaneously. After vaccination was completed the records containing this information were removed to other quarters, so that on subsequent visits the observer had no information as to whether a patient belonged to the vaccinated or the control group. Indi-

throughout. An effort was made to gain uniformity in the designation of cases by accepting for the diagnosis of influenza those individuals who at the time of reporting to sick call had symptoms suggestive of influenza, i. e. rapid onset with mild upper respiratory complaints, chilliness, aches and prostration and were admitted to hospital with sublingual temperatures of 100 F. or more without obvious evidence of other disease. Fresh typical

Cases of influenza were not noted in any dormitory housing inoculated students until at least eleven days after vaccination of the group housed in that dormitory.

viduals who did not receive inoculation of control material were not considered controls. Vaccination was carried out at different times in the various units but in the main was completed by the middle of November. After the group had been vaccinated, new arrivals were not taken into the study. The time of vaccination in relation to the recognized onset of influenza is seen in the subsequent data.

Prior to vaccination and throughout the period thereafter, close observation of all individuals reporting to sick call was maintained by members of the investigating groups. The same type of record card was used

common colds, characteristic follicular tonsillitis and infectious mononucleosis were excluded from the diagnosis of influenza. Owing to local regulations or facilities, certain variations in the requirements for admission to hospital were encountered. In general, however, it appears that the criteria adopted would tend more to the inclusion in the series of cases which were not influenza than to the exclusion of cases which were influenza. While extensive collections of materials for virus and serologic investigation were made, the clinical impressions here stated have not been modified or corrected by any such data.

An epidemic of influenza A was first identified in the Middle West about the second week in November. The disease was subsequently recognized in other localities within a short time thereafter. The epidemic period in the posts under observation was three to four weeks. The disease was, in general, mild, of three to four days' duration and with a low incidence of complications.

The accompanying data represent tabulations of cases called influenza at the time of illness. The designation

cent, while in the 6,263 receiving vaccine there was an incidence of 2.22 per cent, a ratio of 3.2 to 1.

The significance of the results is heightened by the uniformity of trend in practically all instances. The two greatest deviations are noted in the medical school units and in California. In the former the low incidence of the disease is thought to be related to the lack of central reporting. In the latter instance there is no clear difference between control and vaccinated groups; various factors such as furlough, the increased interval since

		Control	690	(11) 12	16	11	40	6.67	79
		Total	1,198				51		

Five cases before vaccination completed. Summarized totals exclude the cases occurring in the first five days following vaccination. Numbers in parentheses indicate those occurring in the first five days. Hemolytic streptococcus pharyngitis occurred concurrently with the outbreak of influenza. Twenty per cent of throat cultures were positive for B. hemolytic streptococcus.

TABLE 6.—Results in Group 6: University of California, Berkeley

Monroe D. Eaton, M.D., and Gordon Melkjohn, M.D. Research Laboratory of the California Department of Public Health, Berkeley, Calif. This study was aided by a grant from the International Health Division of the Rockefeller Foundation.

Epidemic period: 11/26/43-1/15/44.

Diagnosis: All cases hospitalized with acute febrile respiratory disease.

Cases by Weeks Ending												Incidence, per Cent	% of Total
Unit	Date Vaccinated	Number In Study	12/3	12/10	12/17	12/24	12/31	1/7/44	1/15	Total Cases

		Control	435	3	1	10	6	3	4	8	34	7.81	59
		Total	892								58		

About 10 cases of streptococcal infection including 2 with scarlet fever occurred during the influenza epidemic.

The unit was on furlough 12/4 to 12/12/43. A few were away 12/22 to 12/28/43.

has been made purely on clinical grounds without reference to serologic or other virus studies for identification of individual cases. The division according to vaccinated or control was not done until the epidemic period was thought to have been passed. The results for the respective units were compiled by the investigating teams and, in all but 1 instance, a report was submitted to the Office of the Surgeon General of the Army before the evidence obtained in other locations was known.

It is seen that the incidence of clinical influenza in the 6,211 men receiving control material was 7.11 per

vaccination and the protracted incidence of disease may be involved, but no single explanation is offered at present. When these two pronounced deviations are excluded, the ratio of influenza in controls to influenza in vaccinated is 4 to 1. In some of the units, ratios of 5 or 6 to 1 were recorded.

It is of interest to note also that, in general, the difference between vaccinated and control individuals was greatest at the height of the epidemic curve and as the epidemic subsided the differential was less marked.

The results at the College of the City of New York and at Iowa, where vaccination was begun after the

epidemic was in progress, indicate that the effect of vaccine becomes evident in about one week after inoculation. In these instances the attack rates in the vaccinated and controls were not especially different during the first week but then diverged sharply. The duration of the effect is not known.

In this brief report no consideration is given to the results of serologic and virus studies which are under way and which will be incorporated in a subsequent complete report.

SUMMARY

The influence of subcutaneous inoculation of a concentrated inactivated vaccine on the incidence of clinical influenza in a series of Army Specialized Training Program units comprising approximately 12,500 men was studied during the recent epidemic of influenza A. Vaccination done shortly before or even after the onset of the epidemic was found to exert a protective effect with a total attack rate of 2.22 per cent among the 6,263 vaccinated and 7.11 per cent among the 6,211 controls, a ratio of 1 to 3.2. The influence of vaccine was most clearly evident at the height of the epidemic prevalences. The duration of the effect has not been determined.

Council on Foods and Nutrition

ACCEPTED FOODS

THE FOLLOWING ADDITIONAL FOODS HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON FOODS AND NUTRITION OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO ACCEPTED FOODS.

GEORGE K. ANDERSON, M.D., Secretary.

PREPARATIONS USED IN THE FEEDING OF INFANTS (See Accepted Foods, 1939, p. 156).

Beech-Nut Packing Company, Inc., Canajoharie, N. Y.

BEECH-NUT BRAND STRAINED VEGETABLES AND BEEF, WITH RICE AND BARLEY.

Analysis (submitted by manufacturer).—Total solids 13.95%, moisture (by difference) 86.05%, ash 1.25%, fat (ether extract) 0.56%, protein ($N \times 6.25$) 2.91%, crude fiber 0.48%, carbohydrates other than crude fiber (by difference) 8.75%, calcium (as Ca) 0.03%, phosphorus (as P) 0.04%, iron total 7.8 parts per million, iron total available 7.3 parts per million, copper 3.1 parts per million.

Calories.—0.52 per gram; 14.74 per ounce.

Libby, McNeill & Libby, Chicago.

LIBBY'S BRAND HOMOGENIZED APPLE SAUCE.

Analysis (submitted by manufacturer).—Total moisture 85.49%, total solids 14.51%, total ash 0.32%, nitrogen 0.02%, protein ($N \times 6.25$) 0.12%, crude fiber 0.46%, fat (ether extract) 0.02%, salt (as NaCl) 0.18%, total carbohydrates (by difference) 13.59%, calcium 2.18 mg. per hundred grams, copper 0.218 mg. per hundred grams, iron 0.30 mg. per hundred grams, phosphorus 6.22 mg. per hundred grams, lead 0.64 part per million.

Calories.—0.55 per gram; 15.62 per ounce.

Libby, McNeill & Libby, Chicago.

LIBBY'S BRAND HOMOGENIZED BEETS.

Analysis (submitted by manufacturer).—Total solids 10.25%, total moisture 89.75%, total ash 1.29%, nitrogen 0.163%, protein 1.02%, crude fiber 0.478%, fat 0.004%, carbohydrates (by difference) 7.458%, calcium 17.36 mg. per hundred grams, copper 0.145 mg. per hundred grams, iron 1.065 mg. per hundred grams, phosphorus 34.76 mg. per hundred grams.

Calories.—0.34 per gram; 9.63 per ounce.

Libby, McNeill & Libby, Chicago.

LIBBY'S BRAND HOMOGENIZED PEACHES.

Analysis (submitted by manufacturer).—Total solids 15.22%, total ash 0.33%, total moisture 84.78%, nitrogen 0.07%, protein ($N \times 6.25$) 0.44%, crude fiber 0.34%, fat 0.01%, carbohydrates (by difference) 13.17%, salt (as NaCl) 0.15%, calcium 5.5 mg. per hundred grams, copper, 0.20 mg. per hundred grams, iron 1.01 mg. per hundred grams, phosphorus 20.40 mg. per hundred grams.

Calories.—0.58 per gram; 16.55 per ounce.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

AUSTIN E. SMITH, M.D., Secretary.

TYROTHRIN.—An extract, first isolated by Dubos, obtained from *Bacillus brevis*, a gram-positive, aerobic, spore-forming soil organism. Tyrothricin possesses antibacterial action against several species of gram-positive organisms.

Actions and Uses.—Tyrothricin consists of at least two substances, gramicidin and tyrocidin, the former agent being by far the more active component. It seems not unlikely that some of the earlier reports which were claimed to be based on the use of gramicidin were actually concerned with the mixture. Included in the organisms that show some degree of susceptibility are species of pneumococci, streptococci and staphylococci. Its action on bacteria appears to consist, at least in part, of inhibiting enzymatic action, retarding growth and causing lysis of the bacteria against which it is effective. Its standardization is determined at present by the protection afforded mice infected with pneumococci administered intraperitoneally.

Tyrothricin should be applied locally. It is ineffective when administered orally and is ineffective and dangerous when given intravenously. It has been reported to be of value in the treatment of superficial indolent ulcers, the predominating organism of which is gram positive, mastoiditis, empyema and some other wound infections. Its field of usefulness is limited and it appears to exert no effect unless it can come in direct contact with the organisms. Thus it may not exert much effect in the presence of deep-seated infections. Body fluids such as saliva, urine and serum offer a slight inhibiting action, whereas substances from gram-negative organisms are decidedly inhibiting.

It may be used with caution in body cavities as long as there is no direct connection with the blood stream. But in no instance should proper surgical treatment be ignored when it is indicated. It should be remembered that, although tyrothricin appears to have a field of usefulness in medicine, its use is still in an experimental stage and much work remains to be done before its true status is established and final comparisons can be made with other antibiotics and anti-infective agents in general.

Dosage.—Tyrothricin must be applied locally, *not intravenously or by mouth*. It is administered after diluting with sterile distilled water to form an isotonic solution in a concentration which yields 500 micrograms of the drug per cubic centimeter. This concentration is usually effective against the infecting organism, although higher concentrations may be used if indicated. However, higher concentrations may be irritating to the tissues.

SHARP & DOHME, INC., PHILADELPHIA

Tyrothricin Concentrate: 1 cc. ampul of a solution of tyrothricin, 25 mg. per cubic centimeter, accompanied by a vial containing 49 cc. of sterile distilled water which contains phenylmercuric borate in a concentration of 1:50,000; 20 cc. ampul of a solution of tyrothricin, 25 mg. per cubic centimeter, not accompanied by a diluent.

ESTROGENIC SUBSTANCES (See New and Nonofficial Remedies, 1943, p. 401).

The following additional dosage form has been accepted:
THE SMITH-DORSEY COMPANY, LINCOLN, NEB.

Ampul Solution of Estrogenic Substances (in sesame oil) with Benzyl Alcohol 3%: 10 cc. Each cubic centimeter contains the equivalent of 20,000 international units of estrone. Three per cent benzyl alcohol added as a preservative.

THEOPHYLLINE ETHYLENEDIAMINE (See New and Nonofficial Remedies, 1943, p. 356).

The following dosage form has been accepted:

CHEPLIN BIOLOGICAL LABORATORIES, INC., SYRACUSE, N. Y.

Ampul Solution Aminophylline: 0.48 Gm. in 2 cc. and 0.24 Gm. in 10 cc.

VIOFORM (See New and Nonofficial Remedies, 1943, p. 121).

The following additional dosage form has been accepted:

CIBA PHARMACEUTICAL PRODUCTS, INC., SUMMIT, N. J.

Vioform Insufflate: 8 ounce bottles.

SATURDAY, APRIL 1, 1944

DIETARY DEFICIENCY AND POLIOMYELITIS

Clinicians generally agree that a deficiency in vitamins or other essential food elements usually results in a lowered natural resistance to bacterial infections. There is reason to believe that this hyp immunity is largely due to a reduction in phagocytic functions.¹ In contrast with this general agreement the effect of similar nutritional deficiencies on antiviral resistance is still controversial. McCormick,² for example, reported that the diets of victims of infantile paralysis are frequently low in thiamine. He obtained good results in paralytic cases by administering rather large amounts of thiamine. Exactly opposite conclusions were drawn by Ward,³ who found that thiamine excretion in children with paralytic poliomyelitis does not differ from that of normal children. He believes that thiamine nutrition is not a determining factor in poliomyelitis.

Similar contradictions have resulted from a study of experimental poliomyelitis. Working with monkeys, Jungeblut⁴ found that the incidence of paralysis could be reduced by the administration of rather large doses of vitamin C, while Sabin⁵ could not obtain protection from vitamin C therapy. Toomey⁶ found that vitamin D gave almost complete protection when the infective dose of poliomyelitis virus was injected directly into an exposed loop of the intestine of monkeys. Sabin⁷ found that vitamin D did not afford protection under similar conditions and that rachitic monkeys are not more susceptible to experimental poliomyelitis than normal controls.

A new basic theory of the relationship of nutritional factors to virus infection was suggested by Rivers,⁸

Sprunt⁹ and others, who found that rabbits on a starvation diet are more resistant to vaccinia virus than adequately fed controls. Bloomfield and Lew¹⁰ found that vitamin B deficiency protected animals against spontaneous ulcerative cecitis, which was prevalent in their laboratory among animals on adequate diets. Rasmussen¹¹ and his associates of the University of Wisconsin applied this new lead by testing the effects of thiamine deficiency on resistance to poliomyelitis in mice. One group of 35 mice was maintained on a thiamine deficient diet, with 35 controls fed at the presumably optimum thiamine level. Both groups were inoculated intracerebrally with 0.03 cc. of a 2 per cent suspension of Lansing mouse passage poliomyelitis virus. By the fourteenth day 25 of the mice maintained at the optimal thiamine level had developed paralysis. None of the mice on the thiamine deficient diet showed paralytic symptoms. Thiamine deficiency therefore apparently conferred an almost complete poliomyelitis immunity.

This seeming paradox is currently studied in greater detail by Foster and her associates¹² of the Department of Pediatrics, University of Pennsylvania School of Medicine. In a typical experiment two groups of mice were placed for twenty days on diets differing only in thiamine content. The control diet contained 100 mg. of thiamine per hundred grams of food, while the deficiency diet contained but 10 mg. of thiamine per hundred grams. This amount was increased slightly with the onset of signs of thiamine deficiency. Of 79 mice on the high thiamine diet, 60 (75 per cent) developed paralysis by the twenty-first day after intracerebral inoculation with a ten to one hundred 50 per cent mortality dose of the Lansing strain of poliomyelitis virus. Of 77 mice on the thiamine deficient diet only 7 (9 per cent) showed signs of paralysis. Both mortality rate and incidence of paralysis were much lower in the vitamin deficient group.

Since one of the characteristics of thiamine deficiency is loss of appetite with a concomitant decrease in consumption of food, the effect of a simple restriction of daily food intake was tested on 276 mice. Each animal on the restricted diet was given 1 Gm. of food daily, which is about 40 per cent of the normal food consumption. In many of the groups extra thiamine was given in the restricted diet to compensate for thiamine deficiency. The results were similar to those obtained with the earlier thiamine deficient groups. Restriction of caloric intake resulted mainly in a delayed development of paralysis, with a slighter reduction in mortality rate.

As early as 1911 Rous¹³ noted that undernourished chickens are relatively resistant to sarcoma virus. Tannenbaum¹⁴ found that in mice restriction in such essential food components as proteins, vitamins, minerals or fats, as well as simple restriction of caloric intake, increases normal cancer resistance. Bischoff¹⁵ found that in mice a deficiency in pyridoxine (B_6) produces a significant decrease in rate of growth of tumors. The immunizing effect of thiamine deficiency against poliomyelitis virus is thus not an isolated phenomenon but an immunologic reaction operative against other viruses and against tumor cells.

Several plausible theories to account for this phenomenon have been suggested by the Philadelphia pediatricians. Probably the simplest theory is the assumption that the vitamin and other nutritional requirements of a virus are greater or more exact than those of the bacterial cell, an intermediary position being occupied by the normal tissue cell. With a reduced vitamin or caloric intake the multiplication of the virus would first be inhibited without appreciable tissue starvation, giving a seeming increase in natural resistance. Further reduction in nutritional factors would reduce phagocytic activity without inhibiting the normal rate of bacterial growth, with a resulting real decrease in bacterial resistance. Work is being continued along lines suggested by these theories.

RECONDITIONING CONFERENCE AT SCHICK GENERAL HOSPITAL

A sound program for the reconditioning of disabled soldiers, recently announced by the Surgeon General of the Army, was given great impetus in a two day conference held at the Schick General Hospital, Clinton, Iowa, in March. Medical Corps officers and others in attendance were impressed by the scientific approach to the problem. An enthusiastic execution of a realistic reconditioning program during the past several months at Schick General Hospital by its commandant, Col. Dean F. Winn, M. C., and his staff clearly demonstrated the great possibilities of an early return to duty of many disabled soldiers. A first hand opportunity to observe the operation of the plan was afforded by the ward walks and demonstration clinics, and visiting officers were given every opportunity to interrogate patients, trainees, wardmasters, nurses, medical officers and others concerned with the program.

The presence of high ranking Army officers, representatives of the Office of the Surgeon General and members of the War Department General Staff was

indicative of the vital interest of the Army in the successful operation of the plan. Emphasis is placed on the effort to utilize to the fullest extent possible the manpower of the Army. Major Gen. Ray E. Porter, assistant chief of staff, general staff, pointed out that the cream of the nation's crop of young manhood are now in the Army. Young men who will come to the medical department for reconditioning are for the most part trained soldiers who must be quickly restored to military duty or useful civilian occupations. "Every one of them you lose for the Army, every day that one of them remains away from duty longer than is absolutely necessary to his full recovery, is a damning charge against all of us and an irreparable loss to our cause."

Reconditioning, though not a new concept to physicians, has been carefully planned to include all phases of the problem. Last year the Surgeon General, after a thorough study of the problem, created a new division in his office, the Reconditioning Division, and appointed Col. Augustus Thorndike, M. C., as its director. Colonel Thorndike was formerly physician to Harvard, where he had practical experience with athletes. He is the author of a well known book dealing with the care of injuries of athletes and is singularly fitted for the new post. Training for men to be returned to duty as the result of the reconditioning program includes physical reconditioning, educational reconditioning and emotional reconditioning. Physical exercises are begun at the earliest possible time. In many instances they are done while the patient is still in bed; however, in every case they are prescribed by the medical officer in charge of the ward. Strict supervision of the program is maintained by medical officers of the professional services who are responsible for the care of the soldiers. Much of the physical training program is carried out by nonprofessional officers and enlisted men under the direction of medical officers. A graduated system of calisthenics, drills, games and military training is the basis of physical reconditioning. Concurrently, equally well planned programs for educational and emotional reconditioning are carried out by competent personnel. Not only is the disabled soldier to be returned to duty wherever possible physically fit, but the program also calls for such reconditioning as will return him "a tough, seasoned soldier with an aggressive combat spirit."

Here is a challenge to the medical profession to restore as many of the nation's sick and wounded soldiers to duty as early as possible. Sound practical plans including competent personnel and adequate materials have been authorized. The ultimate success of the plan, however, rests with the individual medical officer, whose judgment in each soldier's welfare should rest on accepted scientific principles.

SYMPATOL-STEARN'S—A TRIUMPH OF MEDICAL MISINFORMATION FOR PHYSICIANS

In recent issues of some pharmaceutical and medical periodicals—not too careful about the scientific evidence in support of the claims made—advertisements with the caption “A Standby of European Physicians Comes to America—Sympatol, a *Safe* Circulatory Stimulant.” Embellishing this statement is an artistic presentation of a schematic world map with a broad arrow emanating from a point due west of the Rock of Gibraltar somewhere in the Atlantic Ocean and ending above “Sympatol.” Below this broadside the reader is informed in part:

With the presentation of this renowned European professional product, Stearns fills a widely recognized need of American medicine. For Sympatol is a *safe* circulatory stimulant—free from adverse side reactions on heart and nerves.

As attested by twenty years' experience of leading continental doctors, the bracing, prolonged, tonic effects of Sympatol may be safely employed—with marked benefits—in nearly all cases of low blood pressure . . . during convalescence from colds and “flu” . . . in hypothyroidism and the menopause . . . for “toning up” pale, listless children. This abbreviated list will indicate why Sympatol is regarded, in Europe, as almost indispensable.

If the advertising is to be believed, the “Indications suggesting this circulatory stimulant cover all general debilitated states, which include patients convalescing from colds and ‘flu,’ ‘arrested’ tuberculosis, women in the menopause, listless rundown children, hypothyroids and similar conditions.”

Now the simple plain fact is that Sympatol has been known on the American continent for many years. In 1929 Frederick Stearns & Company presented “*paramethylamino-ethanolphenol hydrochloride*” to the Council on Pharmacy and Chemistry as Sympatol. Subsequently (1930) the Council voted to accept Sympatol with certain provisions, not under this name but under the term Synephrin. Shortly thereafter the firm presented Synephrin Tartrate, described as “the normal tartrate of the synthetic alkaloid Synephrin, *p*-hydroxyphenylmethylaminoethanol.” It will be noted that the latter chemical designation indicates the same base as that which originally bore the name Sympatol. In 1933 the Council gave consideration to a product of Frederick Stearns & Company named Neo-Synephrine, one chemical name for which was stated to be “*levo-methylaminoethanolphenol hydrochloride*”; this product was claimed to represent an improvement over the previously accepted product. The Council voted to accept Neo-Synephrine Hydrochloride for inclusion in New and Nonofficial Remedies and published a statement which appears in the Annual Reports of the Council on Pharmacy and Chemistry, 1934, to the effect that Synephrin Tartrate had been omitted from New and Nonofficial Remedies, but the firm was going

to conduct investigations to “ascertain whether or not it [Synephrin Tartrate] is of clinical value in the treatment of cardiovascular disorders.” The current advertising for Sympatol obviously omits reference to the fact that the product was available on the American market over ten years ago. The reader is led to believe that he is offered something new, something wonderful, something that has been the standby of European medicine. He is also led to believe that this product has been established as a stimulant for a wide variety of conditions; the Council has not received any evidence in substantiation since 1933.

Current Comment

MEDICAL TESTIMONY IN MINNESOTA

Three years ago the Minnesota State Medical Association created a Committee on Medical Testimony to which courts and others may refer instances in which physicians have given questionable medical testimony. The committee, after investigation and if the facts warrant it, may censure the physician, may publicize the circumstances of the particular case or may bring the matter to the attention of the state board of medical examiners for disciplinary action. This experiment has been watched with interest by all who are concerned with finding solutions to the problem of medical expert testimony. Recently the Committee on Medical Testimony referred to the board of medical examiners the case of a physician who had testified as an expert witness for an accused charged with murder. Both the committee and the board concluded that the testimony in question was unjustified. The board found, however, that neither perjury nor monetary gain was a factor in the giving of the testimony, and for that reason the license of the physician was not suspended or revoked. He was censured. In reaching its decision in this case, the board said:

This board is of the opinion that no physician has a right to practice medicine just as he pleases, nor to testify in court in a similar fashion. We believe that a physician's testimony should be based upon a factual background that has been carefully scrutinized by the physician before he expresses his opinion. This opinion should be reasonable and surrounded by every mark of truthfulness and sincerity. Under those circumstances the opinion is of value to courts and juries alike. The scrutiny required is all the greater where the defendant is on trial for murder and the history of any physical or mental abnormalities is furnished by the defendant or some one close to him.

Next to saving life and giving aid to the sick and injured no greater responsibility devolves on the medical profession than giving testimony in court or elsewhere. The right of a physician to continue in the practice of medicine is measured not only by his professional competence as a physician but also by what he says and does as a physician.

EFFICACY OF VACCINATION AGAINST YELLOW FEVER

Previous investigations have shown that mass vaccination of human beings against yellow fever with the attenuated strain of yellow fever virus known as 17D is an effective method of producing immunity. This virus has become available for widespread clinical trial comparatively recently, and only now is the duration of immunity attained susceptible of evaluation. Bugher and Gast-Galvis,¹ who studied the efficacy of yellow fever vaccination in Colombia, report that there has been only 1 recognized case of yellow fever among over 600,000 persons vaccinated with the 17D strain. A boy had been inoculated only five days before becoming ill; consequently he was apparently in the incubation period of the disease at the time of inoculation and could not have been expected to produce demonstrable antibodies in time to ward off the disease. In contrast to this extraordinary record, 198 proved and 45 probable cases were recognized among unvaccinated persons from 1937 to 1943, the former year being that in which vaccination was begun. A large number of these cases, furthermore, occurred in known endemic areas in which over 90 per cent of the population had been vaccinated. These observations are crucial: yellow fever continued to appear in the small unvaccinated fraction while disappearing among those inoculated. Cases of the disease were continuing to appear in the unvaccinated minority during 1941 and 1942. On clinical grounds it can be concluded, therefore, that effective immunity from vaccination with the 17D strain persists for at least four years. Since there has not been any clinical evidence of a break in the protection at the end of four years, immunity will probably continue for an unknown further period.

ROCKEFELLER FOUNDATION IN 1943

Especially noteworthy in President Fosdick's review¹ of the work of the Rockefeller Foundation in 1943 is the part played by the foundation's grants in the development of penicillin. Thus it is reported that grants have been made since 1936 to Dr. H. W. Florey at Oxford for investigations to be carried out by him and his colleagues on this substance. The foundation has given uninterrupted support to Svedberg's work on proteins at the University of Uppsala and to Runnström's research in chemical physiology and embryology at the University of Stockholm. In Switzerland the foundation has made grants for research in biochemistry, biophysics and neurophysiology. Keeping alive the flame is an uphill fight, however; as Fosdick says, "Laboratories surrounded by barbed wire are ugly monuments to the intellectual and moral distortion of our times." Other matters of importance discussed in this report deal with the return of the gambiae mosquito to Brazil—apparently brought by plane from

Accra and Dakar in Africa to Natal—the reopening of the foundation's laboratory in Lagos, West Africa, for the study of the epidemiology of yellow fever, and vitally important investigations on typhus. Scientific as well as personal tragedy is abroad in the world: At the fall of Manila the Japanese looted the foundation's office and destroyed all records; in China Dr. Henry S. Houghton, director of the Peiping Union Medical College, and Mr. Trevor Bowen, its comptroller, are still imprisoned with little hope for their early return, while the buildings of the college have been taken over by the military and the greater part of their contents removed. When return to the blacked out areas of the world is again possible, the Rockefeller Foundation will doubtless appear in the forefront of the agencies seeking to restore the bases of civilization.

U. S. P. VITAMIN MIXTURES

The value of vitamin mixtures in multiple vitamin deficiencies is well established. Numerous communications have provided much information on the administration of these mixtures; the Council on Pharmacy and Chemistry has outlined the type of mixtures¹ that will be found acceptable for inclusion in New and Nonofficial Remedies. Two such vitamin mixtures, Hexavitamin and Triasyn B in capsules and tablets, are described in the first bound supplement to U. S. P. XII. Hexavitamin contains vitamin A from natural (animal) sources, vitamin D from natural (animal) sources or as activated ergosterol or activated 7-dehydrocholesterol, ascorbic acid, thiamine hydrochloride, riboflavin and nicotinamide. Triasyn B consists of thiamine hydrochloride, riboflavin and nicotinamide. For those who desire therapeutically effective vitamin mixtures not disguised by a multiplicity of nonrevealing and frequently therapeutically suggestive names, Hexavitamin and Triasyn B are important additions to U. S. P. XII. The next step will be for the physician to prescribe such compounds for his patients so that they may be obtained from the pharmacist.

RABID FOXES IN MARYLAND

According to newspaper report, rabies has broken out in near epidemic proportions among foxes in Maryland. In several cases rabid foxes have attacked human beings: a railroad trainman, a farmer and a bus driver have been specifically mentioned. Twelve soldiers at Fort Meade, Maryland, were given treatment for the prevention of rabies after one of the post's puppy mascots had been infected. The state game warden has declared an open season on fox hunting, subject to the local laws in eleven counties which have regulations protecting these animals. In this case the ancient sport of fox hunting and public health prophylaxis seem to go hand in hand.

MEDICINE AND THE WAR

In this section of The Journal each week will appear official notices by the Committee on War Participation of the American Medical Association, announcements by the Surgeons General of the Army, Navy and Public Health Service, and other governmental agencies dealing with medicine and the war, and such other information and announcements as will be useful to the medical profession.

MILITARY MOBILIZATION AND TUBERCULOSIS CONTROL

Colonel Esmond R. Long
MEDICAL CORPS, ARMY OF THE UNITED STATES

Captain Charles F. Behrens
MEDICAL CORPS, U. S. NAVY

Colonel Roy A. Wolford
MEDICAL CORPS, ARMY OF THE UNITED STATES,
VETERANS ADMINISTRATION

Senior Surgeon Herman E. Hilleboe
U. S. PUBLIC HEALTH SERVICE

Colonel Leonard G. Rowntree
MEDICAL RESERVE, SELECTIVE SERVICE SYSTEM

The current military mobilization, which requires preinduction physical examination, has furnished a unique opportunity to promote national tuberculosis control. The following paragraphs indicate the manner in which advantage is taken of the opportunity through the combined efforts of the Selective Service System, the Army, the Navy, the U. S. Public Health Service and the Veterans Administration.

REJECTION FROM MILITARY SERVICE

In normal procedure men selected through the operation of the Selective Service System are sent to an armed forces induction station, jointly controlled by the Army and Navy, where they are given a physical and x-ray examination of the chest in the course of a complete physical examination. X-ray examination is ordinarily by the method of photoroentgenography, with stereoscopic 4 by 5 inch films; whenever there is reason, however, to supplement this rapid method by further x-ray observation, examination with full size films is made.

The standards for acceptance for military service are specified in Army and Navy regulations. They require exclusion of all active tuberculosis, and all latent tuberculosis that might be reactivated under military conditions. They permit acceptance of small well scarred tuberculous lesions, limited to densely calcified residues of childhood disease, or minimal strandlike remains of tuberculosis of reinfection type after repeated examination has indicated stability of the lesion. Men who fail to meet the standards are rejected, and notification of the cause of rejection is made on the Selective Service System form (DSS Form 221) accompanying each man. Men who meet the standards are forwarded at a later date to an Army reception center or Navy training station for induction and military duty.

FOLLOW-UP OF REJECTED MEN

The Selective Service System has taken measures to refer men rejected for tuberculosis to state public health agencies for follow-up with a view to isolating open cases, finding new cases among contacts and instituting suitable supervision of all contacts. The first steps in this direction were made in May 1942, when the director of the Selective Service System issued instruction to all local boards making provision whereby x-ray films of men rejected for military service because of nonremediable chest disease could, within the discretion of the state director of the Selective Service System, be delivered to state health officers for public health purposes. Subsequent arrangements for reporting cases of tuberculosis and at the same time furnishing the films of rejected men to the state health departments were made in many states.

A review of the degree of cooperation a year later, i. e., in May 1943, by the Tuberculosis Control Section of the U. S. Public Health Service brought out the fact that state health departments in forty-seven of the forty-eight states and in the District of Columbia were provided with at least the names and addresses of men rejected because of tuberculosis. Twenty-four of the states received the chest x-ray film on which rejected was based, in addition. As a rule reports and films are sent from state Selective Service System headquarters directly to the state health department.

In twenty-five of the forty-eight states and in the District of Columbia at the time the review was made follow-up on the cases reported was recorded by the state health officers as complete. In twenty-one states only partial follow-up was practiced. In the remaining states arrangements for follow-up had not been made. The chief reason given for inadequacy or failure of follow-up was shortage of local personnel. In numerous states the state and county affiliates of the National Tuberculosis Association have performed effective service in supplementing the work of the state and city health departments.

In this connection it is worth pointing out that in the face of personnel shortage effective review and follow-up of cases can be made only through definite organization of those interested in the field. It is believed that an adequate survey within states will reveal additional assistance which can be coordinated by county health officers into successful working teams.

REVIEW BOARDS

In many of the states, at the present time, state headquarters of the Selective Service System have established review boards for the verification of diagnosis in men rejected for tuberculosis, with a view to reconsideration of inactive cases in which the evidence for final rejection is not convincing. The review system varies in different states, but as a rule it involves study of films and pertinent clinical facts by a board or boards of tuberculosis and x-ray specialists, and recommendation, through appropriate channels, of needed medical care in the case of men with active or potentially active disease and of resubmission of men by local boards to induction stations in the case of registrants who are, in the judgment of the board, able to perform military service. In the latter case the procedure is the same as in the original appearance of the man concerned. He is again examined at an armed forces induction station and may be accepted or again rejected, according to the decision of the induction station examining board. When the lesion is of "borderline" character, men are frequently accepted on the basis of the fortification of opinion furnished by the review board's recommendation.

In some states review boards other than those constituted through Selective Service System action have been established by special arrangement between the induction station and chest specialists in the local medical profession. Through these boards the same purposes are accomplished.

CASE FINDING IN THE ARMED FORCES

Case finding does not stop with the preinduction x-ray examinations. The latter have not been perfect, and a certain number of cases of active tuberculosis have failed to be detected by the induction station examination. There are various reasons. The volume and necessary speed of the examinations are in large part responsible. The failure to exclude all cases has been a cause of serious concern in the Army and Navy, and appropriate arrangements for avoiding all possible errors have been made. These appear increasingly effective.

Experience has shown that a large proportion of the tuberculous cases missed at the induction stations are discovered within the first few months of service, before substantial change has taken place in the extent of the disease. These cases are found in the course of certain required physical examinations, as in Officer Candidate Schools or in hospitals in the course of general or special physical examination.

Active cases discovered in the Army and Navy receive initial treatment in station and general hospitals, but, since active tuberculosis disqualifies for any form of military service, enlisted men are generally discharged at an early date to the Veterans Administration. Special arrangements for longer care are at present in effect at Fitzsimons General Hospital for commissioned officers, noncommissioned officers of the first three grades and enlisted men nearing twenty years of service in the Army, and for certain Navy personnel.

Of the millions of men called for military service or appearing for voluntary enlistment in the last three years the great majority have had a chest x-ray examination. Figures have not yet been released on the total number rejected at recruiting and induction stations. The rate has varied slightly with minor changes in regulations. During the first part of 1943 the rejection rate for tuberculosis was approximately 1.4 per cent.

Through the close cooperation here described between the armed forces induction stations, state and local Selective Service units and state and county health departments, an effective program is being developed for rejectees which should save many individual lives and have far reaching effect on the control of tuberculosis.

The system in operation also ensures that men whose lesions escaped detection before induction and men who develop new tuberculosis in the armed services will sooner or later be discovered. As indicated in the preceding paragraphs, detection is frequent in the early months of service. Chest x-ray examination at discharge, required in both the Army and the Navy, enables discovery of those whose lesions were not detected earlier.

CARE BY VETERANS ADMINISTRATION

With rare exception all soldiers and sailors discharged from service by reason of tuberculosis are entitled to care at the hands of the government. Up to Dec. 31, 1943 the Veterans

Administration had adjudicated the claims of 4,858 enlisted men who entered service in the Army, Navy, Marine Corps or Coast Guard after the declaration of a national emergency on Aug. 17, 1940 and were discharged from service because of tuberculosis. In 2,838, or 58.4 per cent, of these cases claim for disability pension was allowed. The 2,838 allowed cases were divided as follows: Army 87.2 per cent, Navy 10.4 per cent, Marine Corps 1.5 per cent, Coast Guard 0.9 per cent. Regardless of decision as to service connection of the lesion and claim for pension, soldiers and sailors are eligible for care in veterans facilities in accordance with Public Law 10, 78th Congress, enacted March 17, 1943, which provides that any person serving in the active military or naval service of the United States between Dec. 7, 1941 and the termination of hostilities of the present war and not dishonorably discharged will obtain at discharge the status of a "veteran of any war" and thus be eligible for hospitalization as a beneficiary of the Veterans Administration. The Veterans Administration maintains thirteen tuberculosis hospitals and additional beds for tuberculosis in twenty-six general hospitals. On Jan. 31, 1944 a total of 6,114 beds were available for tuberculous veterans, including those of World War I.

COOPERATION BETWEEN SERVICES

Continued improvement is being made in the separate phases of the program here outlined, to the end that maximum utilization may be made of the unusual opportunity for tuberculosis control. Through informal but efficient arrangement representatives of National Headquarters, Selective Service System, the Medical Corps of the Army, the Medical Corps of the Navy, the Tuberculosis Control Section of the U. S. Public Health Service and the Office of the Medical Director of the Veterans Administration meet at regular intervals to consider, recommend and effect improvements in this cooperative enterprise. The National Tuberculosis Association, National Research Council, the American Legion and other organizations are cooperating with these bodies in active measures for the education of men rejected or discharged from the military services by reason of tuberculosis, ensuring their understanding of the great importance of their own care and the necessity of preventing transmission of their disease to others.

ARMY

PENICILLIN TREATMENT OF RESISTANT GONORRHEA

Because of the adequacy of supplies of penicillin available to the Army, persons with sulfonamide resistant gonorrhea will not be transferred to general hospitals for treatment except when indicated by complications, according to the Technical Bulletin of Medicine, No. 16, issued by the War Department recently. Station hospitals should requisition any additional supplies of penicillin needed for this purpose from the nearest general hospital. Penicillin will be administered to persons with gonorrhea immediately after failure to respond to one course of a sulfonamide compound. There is still insufficient evidence to justify the use of penicillin in any of the venereal diseases other than gonorrhea, and it will not be used for such treatment except when specifically authorized by the Surgeon General.

CENTER FOR TREATMENT OF ARTHRITIS

A center for the diagnosis and treatment of arthritis has been set up at the Army and Navy General Hospital, Hot Springs National Park, Ark., the War Department recently announced. All patients with severe and prolonged arthritis to be treated by the Army will be sent to the hospital, which is specially equipped for treatment of diseases of the joints and has facilities for extensive physical therapy. Lieut. Col. Philip Hench, formerly of the Mayo Clinic, is in charge of medical service at the hospital. Dr. Hench is a leading specialist and an authority on diseases of the joints. While arthritis does not account for a large percentage of illnesses in the Army, it is found to be one of the most disabling.

FIRST AID, SANITATION AND PERSONAL ADJUSTMENT COURSES

Emphasizing that malaria, diarrheal diseases and neuropsychiatric disorders are each responsible for a large part of hospital admissions, the War Department has issued instructions that every officer, noncommissioned officer and enlisted man be given standard courses of instruction in first aid, sanitation and personal adjustment. Material for the personal adjustment courses for all ranks—a new topic in military education—is being distributed by the Surgeon General as rapidly as it can be prepared.

The commanding generals of the Army Ground, Air and Service Forces have been ordered to provide such inspections and tests as will assure the attainment and maintenance of the appropriate minimum standards of proficiency in first aid, sanitation and personal adjustment by all commissioned and enlisted personnel. At least one inspection and test will be made within the six months preceding the departure of a unit overseas.

The department has instructed that "appropriate command action" be taken in the cases of all officers and noncommissioned officers who do not attain the prescribed minimum standard of proficiency.

It has also been ordered that refresher courses in the three topics be given in all officer pools, at overseas replacement depots and in staging areas.

To attain the prescribed standards a thirty-three hour instruction course for enlisted men of the lower grades has been outlined. For noncommissioned officers and company officers a twenty-six hour course is outlined, designed to give such per-

J. A. M. A.
April 1, 1944

sonnel a teaching knowledge of sanitation and first aid and to enable them to recognize signs and symptoms of poor mental health and to know the causes of mental breakdowns.

The thirty-three hour enlisted men's course will include twenty hours during which such phases of sanitation as personal hygiene, sex hygiene, mess sanitation, control of intestinal diseases, water purification, malaria control and the like will be covered; ten hours of first aid, and three hours of personal adjustment lectures, including personal adjustment problems, recognition and handling of emotions and feelings and a healthy point of view toward service life.

The twenty-six hour course is similar, twelve hours being given to sanitation, eight hours to first aid and six hours to personal adjustment lectures.

The War Department stated that the degree to which commanders of all echelons preserve the fighting strength of their units by maintaining the health of their men is a measure of their leadership ability. "The unit surgeon is a staff officer of essential importance," the department stated. "He is not provided for the sole purpose of administering to the sick and injured. His primary responsibility is to advise his commander how the personnel of the command can be kept physically and mentally well."

THREE OFFICERS OF NURSE CORPS AWARDED SILVER STAR

Three officers of the Army Nurse Corps were recently awarded the Silver Star, the first women in the history of the United States to receive that decoration, for heroism during action on the Fifth Army's Anzio-Nettuno beachhead in Italy. The awards were presented at a joint ceremony in Italy by Major Gen. John P. Lucas, U. S. Army, to 1st Lieut. Mary L. Roberts, Dallas, Texas, 2d Lieut. Elaine A. Roe, Whitewater, Wis., and 2d Lieut. Rita Virginia Rourke, Chicago. All three were cited for their coolness and efficiency during a concentrated shelling in February of a field hospital area. Nurses were killed and many among other military personnel were wounded, power lines were cut and doctors and nurses were forced to work by flashlight in the treatment and evacuation of the wounded.

The citation accompanying Lieutenant Roberts' award read as follows:

"Lieutenant Roberts exhibited exceptional coolness and outstanding leadership, reassured the nurses under her charge and encouraged and urged them to greater efforts. Despite the impairment of facilities and the prolonged shelling, the vital work at three operating tables was continued under the inspiration of her conduct and example.

"The actions of Lieutenant Roberts in a critical situation assured the uninterrupted continuation of activities and contributed in a large measure to the success of the operations. Her bravery and unfaltering devotion to duty and complete disregard for her own welfare are in the best traditions of the military service and reflect the highest credit on herself and the Army Nurse Corps."

The citation given jointly to Lieutenant Roe and Lieutenant Rourke read in part as follows:

"Working with flashlights, Lieutenant Roe and Lieutenant Rourke immediately began the orderly evacuation of patients while quieting others who had become alarmed and were attempting to leave their beds.

"Throughout the shelling, which included many air bursts, they exhibited remarkable coolness and courage and carried on with complete disregard for their own safety. The quick thinking, competence under unnerving conditions, and the loyal considerations of Lieutenants Roe and Rourke for the welfare of their patients, prevented confusion which might have been critical, and were an inspiration to the enlisted men working under their supervision."

Lieutenant Roberts is a graduate of Hillman Hospital School of Nursing, Birmingham, Ala. She entered the Army at Fort Sam Houston, Texas, May 19, 1942.

Lieutenant Roe is a graduate of Mary Thompson Women's and Children's Hospital, Chicago. She entered the Army Nov. 10, 1942 at Camp Grant, Ill.

Lieutenant Rourke is a graduate of Providence Hospital, Washington, D. C. She entered the Army Dec. 1, 1942 at Percy Jones General Hospital, Battle Creek, Mich.

LIEUT. COL. WILLIAM A. HUTCHINSON AWARDED LEGION OF MERIT

Lieut. Col. William A. Hutchinson, formerly of Texarkana, Ark., was posthumously awarded the Legion of Merit by the War Department "for exceptionally meritorious conduct in the performance of outstanding service as surgeon for the Eritrea Service Command from May 1942 to February 1943. The difficult and varied terrain in the area covered by this command created a diversity of climatic conditions which caused unusual health problems. Colonel Hutchinson established a highly efficient medical service for both military and civilian personnel, enforcing a rigid health control which was of great importance to the success of local operations. His work in the control of malaria, which was one of the most common health hazards, and his systematic sanitation of all water supply points were outstanding accomplishments. By his exceptional professional skill, untiring efforts and effective methods of operation, Colonel Hutchinson contributed in a marked degree to the successful operation of the United States Army forces in Eritrea." Dr. Hutchinson graduated from Tulane University of Louisiana School of Medicine, New Orleans, in 1924 and entered the service in May 1941. He was reported killed in an airplane crash Feb. 23, 1943.

BRIG. GEN. EUGEN G. REINARTZ RECEIVES THE JOHN JEFFRIES AWARD

Brig. Gen. Eugen G. Reinartz, commandant of the Army Air Forces School of Aviation Medicine, Randolph Field, Texas, was presented with the John Jeffries Award for 1943 recently. This honor is awarded by the Institute of Aeronautical Sciences "for outstanding contribution to the advancement of aeronautics through medical research." The award was presented by Major Gen. David N. W. Grant, air surgeon of the Army Air Forces. General Reinartz has had the longest continuous service of any medical officer assigned to the Army Air Forces, having known no other service in more than twenty-six years of military duty.

The award honors the memory of Dr. John Jeffries, an American physician, who with the French balloonist Blanchard made the first aerial voyage across the English Channel in 1785 and on a previous voyage made the earliest recorded scientific observations from the air. The award was established by the institute in 1940 to give recognition to the importance to aviation of scientific endeavor in the field of medicine.

ARMY NURSE CORPS

Lieut. Col. Ida W. Danielson, A. N. C., who was formerly in charge of personnel for the Army Nurse Corps, has assumed the post as director of nursing in the European theater of operations, succeeding Lieut. Col. Margaret E. Aaron, who has been returned to the United States because of illness. Succeeding Colonel Danielson as chief of nursing personnel is Major Nola Forrest, who for the past eight months has been in charge of nursing services in the California-Arizona Training Center.

FLIGHT SURGEONS' ASSISTANTS

A class of one hundred and twenty-one flight surgeons' assistants completed the six weeks course in aviation medicine at the School of Aviation Medicine, Randolph Field, Texas, March 6. Brig. Gen. Eugen G. Reinartz, U. S. Army, is commandant of the school.

ARMY PERSONALS

Dr. Midian O. Bousfield, formerly of Chicago, first Negro member of the Board of Education and former field medical director of the Rosenwald Foundation, has been promoted from lieutenant colonel to colonel.

Dr. Roscoe C. Giles, first Negro graduate of the Cornell University Medical College, New York, 1915, has been promoted from major to lieutenant colonel.

PROCUREMENT AND ASSIGNMENT SERVICE FOR PHYSICIANS,
DENTISTS AND VETERINARIANSTHE SUPPLY OF INTERNS AND
RESIDENTS

The failure of hospitals to take the steps necessary to obtain deferment of one third of the commissioned officers serving as interns who have been called to active duty for the month of April has produced a serious lag in the 9-9-9 Intern-Resident Deferment Program. The Directing Board of the War Manpower Commission's Procurement and Assignment Service for Physicians, Dentists, Veterinarians and Nurses has sent a letter to its state chairmen for physicians and to hospital superintendents calling attention to the seriousness of the situation.

The effects of this failure, the Directing Board maintains, may not be felt immediately, but by July 1 hospitals will feel seriously the results of failure to obtain the deferment from active duty of the total number permitted under the agreement reached by the Procurement and Assignment Service with the Surgeons General. Under this agreement the Procurement and Assignment Service can obtain deferments from active duty of one third of the commissioned officers who are completing nine month internships in order to insure filling of essential junior residencies. It also can obtain deferments for one half of the commissioned officers serving in junior residencies for service in nine month senior residencies.

Of the group of commissioned officers serving as interns and called to active duty after January 1 and before April 1, deferments have been obtained for the one third permitted by the Procurement and Assignment Service-Surgeons General agreement.

The total number of deferments from active duty of those called to active duty in April fell short of the one third permitted. Even if the Central Office Procurement and Assignment Service had received in time all the applications for deferment of interns and residents which were ultimately submitted, the total number of these requests would still not have equaled one third of the total number called to active duty. This means that hospitals are not finding the physicians who have graduated at odd dates and who therefore complete their internships at odd dates. This also means that medical manpower is not being utilized most effectively.

Still another difficulty develops from the fact that deferment application forms are being received by the central office so late that action cannot be taken under the agreement already mentioned. During the past thirty days 50 per cent of all applications for deferment of interns and residents were received too late for action.

Perhaps the most serious result is the complete loss to civilian hospitals of the services of those individuals who might have been deferred but who are now called to active duty. Each physician going on active duty in April, who might have been deferred, means a loss to civilian hospitals of thirteen and one-half months of service by that physician. This April group was of vital importance, since it is the only large group between January and July from which hospital service could be obtained to cover the shortage period from July to October of this year.

Equally serious is the failure to submit deferment application forms on time. The Procurement and Assignment Service has had excellent cooperation from the Surgeons General. The Surgeon General of the Army, as a matter of fact, requested the Adjutant General to revoke April active duty orders for one half of the men for whom deferment requests were submitted after the deadline. Each case in which the Surgeon General is asked to request revocation of active duty orders from the Adjutant General increases the work load of both

Dr. Bousfield graduated from Northwestern University Medical School, Chicago, in 1909. Both officers are serving at Fort Huachuca, Ariz.

Dr. Julius L. Sandhaus, who has been stationed in England for the past fourteen months, was recently promoted to the rank of lieutenant colonel. He graduated from Jefferson Medical College of Philadelphia in 1936 and entered the service as a first lieutenant in January 1941.

offices and also seriously affects the agreement reached between the Procurement and Assignment Service and the Surgeons General.

The lists appearing in *THE JOURNAL* have been dwindling from week to week. This creates the impression that civilian hospitals do not need the services of one third of the commissioned officers being called to active duty at the termination of their internships.

Hospitals should take certain definite steps:

1. They should determine the exact dates on which commissioned officers who graduated on odd dates will complete their internships.

2. They should also determine for their own information the exact dates on which other commissioned interns will be called to active duty.

3. Even if they do not have a need for the services of these interns in junior residencies, they should assist other hospitals which are short of essential residents to obtain the services of these commissioned officers.

4. To assist other hospitals, this information should be sent to the state chairmen for Physicians, Procurement and Assignment Service, within the next thirty days so that the state chairmen will be able to refer the names of commissioned officers eligible for junior residencies to hospitals in need of their services.

5. Hospitals in need of residents can protect themselves by getting in touch with commissioned officers serving internships in sufficient time to obtain their deferments for junior residencies.

6. Hospitals requesting deferments from active duty must fill out and forward forms 218-Revised (Application for Deferment of Interns and Residents) in sufficient time to have them favorably considered by the Surgeons General—four months before completion of hospital service.

If the 9-9-9 Intern-Resident Deferment Program is to be continued there must be an immediate increase in the cooperation between hospitals in order to insure effective utilization of medical manpower. There must also be an increase in the cooperation between hospitals and the state chairmen of the Procurement and Assignment Service.

HOSPITALS NEEDING INTERNS
AND RESIDENTS

The following hospitals have indicated to the Council on Medical Education and Hospitals that they have not completed their house staff quota allotted by the Procurement and Assignment Service:

(Continuation of list in *THE JOURNAL*, March 25, p. 928)

FLORIDA

St. Luke's Hospital, Jacksonville. Capacity, 224; admissions, 7,763. Mr. W. E. Arnold, Executive Director (1 intern—July 1).

ILLINOIS

Mercy Hospital, Chicago. Capacity, 360; admissions, 7,701. Sister M. Redempta, R.N., Superintendent (1 intern).

IOWA

Broadlawn, Polk County Hospital, Des Moines. Capacity, 174; admissions, 2,823. Mr. T. P. Sharpnack, Administrator (interns—April 1, October 1).

PENNSYLVANIA

Philadelphia Hospital for Contagious Diseases, Philadelphia. Capacity, 1,077; admissions, 3,444. A. C. LaBoccetta, Acting Superintendent and Medical Director (3 residents).

MISCELLANEOUS

WARTIME GRADUATE MEDICAL MEETINGS

Additional subjects and speakers for Wartime Graduate Medical Meetings have just been announced:

At Halloran General Hospital, Staten Island, N. Y.: Low Back Pain, Dr. Philip D. Wilson, April 11.

At Station Hospital, Fort Niagara, N. Y.: Knee Disabilities, Dr. Pio Blanco, April 5; Acute Anterior Poliomyelitis, Dr. Francis Gustina, April 12.

At Grand Central Palace, New York City: Peripheral Vascular Disease, Dr. A. Wilbur Duryee, April 7; General Surgical Approach to the Abdomen, Dr. John F. Erdmann, April 14 and 21; Disorders of the Low Back, Dr. Arthur Krida, April 28.

At Camp Shanks, Orangeburg, N. Y.: Surgical Bacteriology in the Treatment of Surgical Infections, Dr. Frank L. Meleney, April 6; Present Status of Use of Sulfonamides in Surgery and Medicine, Dr. Walsh McDermott, April 13; Anesthesia, Dr. Emery A. Rovenstine, April 20; Neuropsychiatric Problems in the Army, Col. William C. Porter, April 27.

At Camp Upton and Mason General Hospital, New York: Cardiac Irregularities, Dr. Harry Gold, April 3.

At Camp Kilmer, N. J.: Blood and Plasma Bank and the Use of Its By-Products, Lieut. Clifford K. Murray, April 10; Psychosomatic Aspects of Hypertension, Dr. Edward Weiss, April 24.

At England General Hospital, Atlantic City, N. J.: Dysentery, Dr. William Sawitz, April 4.

At Fort Monmouth, N. J.: General Public Health Aspects of Venereal Disease Control, Dr. Norman Ingraham, April 5; Yellow Fever, Dr. William Sawitz, April 12; Fundamentals of Anesthesia, Dr. Frederick P. Haugen, April 19; Peripheral Nerve Block, Lieut. Comdr. Don Hale, April 26.

At Indiantown Gap, Pa.: Basic Concepts in the Treatment of Burns, Dr. Jonathan Rhoads, April 5; Treatment of Burns and the Closure of Surface Defects by Skin Grafts and Flaps, Dr. Hans May, April 12; Viral Pneumonia, Dr. Truman Schnabel, April 19; Yellow Fever, Dr. William Sawitz, April 26.

At Naval Hospital, Philadelphia: Pericarditis, Dr. Thomas M. McMillan, April 14; Digitalis Therapy, Dr. William D. Stroud, April 14; Rickettsial Infections, Dr. William Sawitz, April 28.

At Camp Lee, Va.: Laboratory Aspects of Tropical Diseases, Dr. J. H. Scherer, April 6; Malaria (Clinical Manifestations and Therapy), Dr. Carlton J. Casey, April 14; Plastic and Maxillofacial Surgery, Dr. Guy Harrison, April 21; Respiratory Diseases and Their Treatment by Chemotherapeutic Agents, Capt. Paul S. Strong, April 28.

At Woodrow Wilson General Hospital, Staunton, Va.: Prevention and Treatment of Wound Infections, Dr. William H. Parker, April 6; Drainage of the Pleura with Particular Relation to Chest Injuries, Dr. I. A. Bigger, April 13.

At Camp Pickett, Virginia: Respiratory Diseases and Their Modern Treatment, Dr. Porter P. Vinson, April 6; Prevention and Treatment of Wound Infections, Lieut. Col. Harlan H. Taylor, April 12; Shock and Burns, Lieut. Comdr. Arthur J. Mourot, April 14; Traumatic Surgery of the Abdomen, Lieut. Col. W. R. Galbreath, April 19; War Wounds of the Genitourinary Tract, Major William Bisher, April 21.

At Fort Eustis, Va.: Amputations, Upper and Lower Extremities, Comdr. H. C. Felt, April 13; Psychosomatic Medicine, Dr. Louis A. Schwartz, April 27.

At Norfolk Naval Hospital, Portsmouth, Va.: Newer Drugs and Their Uses in Practice, Major Paul L. McLain, April 12; Peripheral Nerve Injuries, Dr. Claude C. Coleman, April 26.

At Langley Field, Virginia: Psychiatric Problems in Military Service, Dr. John A. Rose, April 4; Military Surgery, Col. Daniel L. Borden, April 11; Treatment of Trauma to the Chest (demonstrated with motion pictures) Major Leonard Bush, April 18; Aviation Medicine, General, Dr. Ludwig Lederer, April 25.

At Ashford General Hospital, White Sulphur Springs, W. Va.: Allergy with Special Reference to Asthma (clinical presentations and ward rounds), Dr. Oscar Swineford Jr., April 3; Arthritis (clinical presentations and ward rounds), Dr. Ralph Pemberton, April 10.

At Fort George G. Meade, Maryland: Lung Injuries, Comdr. L. E. Gilje, April 14; Aviation Medicine with Special Reference to the Cardiovascular System, Dr. Walter A. Bloedorn, April 21; The Use of Sulfamerazine in Dysentery, Dr. Lay Martin, April 28.

At Fort Belvoir, Virginia: Traumatic Surgery of the Abdomen, Capt. Joseph E. Hamilton, April 3; Peripheral Nerve Injuries (demonstrated with motion pictures), Major Barnes Woodhall, April 10; Diagnosis and Treatment of Shock, Lieut. Col. D. B. Kendrick Jr., April 17; New Chemotherapeutic Agents and Their Uses in Practice, Dr. Harry F. Dowling, April 24.

At Newton D. Baker General Hospital, Martinsburg, W. Va.: New Chemotherapeutic Agents and Their Uses in Practice, Dr. Russell A. Nelson, April 3; Dysenteries, Dr. Moses Paulson, April 10; Malaria, Dr. Walter A. Baetjer, April 17; Virus and Bacterial Pneumonias and Their Treatment, Dr. Warfield T. Longcope, April 24.

At U. S. Naval Hospital and U. S. Naval Academy Dispensary, Annapolis, Md.: Amputations, Upper and Lower Extremities, Lieut. Col. Martillus H. Todd, April 21.

At United States Naval Hospital, Bainbridge, Md.: Clinic in Traumatic Surgery, Lieut. Col. Firmadge K. Nichols, April 6; Clinic in Orthopedic Surgery, Dr. H. L. Skinner, April 13.

HOSPITAL SHEETING FOR MATTRESS PROTECTION

The U. S. Department of Commerce, National Bureau of Standards, recently issued a pamphlet on Hospital Sheeting for Mattress Protection, Commercial Standard CS114-43, which was accepted by the trade as its standard of practice for new production beginning Dec. 1, 1943. A recommended commercial standard for this commodity was adopted at a joint meeting of a committee of manufacturers of hospital sheeting for mattress protection and a committee of the American Hospital Association, March 25, 1943. The purpose of this commercial standard is to serve as a guide to producers, distributors and users of sheeting impervious to moisture used for the protection of hospital mattresses. It also provides a basis for clear understanding among producers, distributors and purchasers, and for specifying and guaranteeing the quality of such sheeting.

MILK SUGAR PRODUCTION

Because milk sugar production this year will not be sufficient to meet the requirements of all users, the War Food Administration has issued FDO 95 to direct milk sugar to most essential purposes. Effective April 1, FDO 95 requires approval by the director of distribution for use of milk sugar for any purposes. Under the order, authorization to accept delivery and use of milk sugar must be requested on forms supplied by WFA's office of distribution. When approval is granted, the supplier will be notified of the quantity he can supply under the order. The total estimated requirements for milk sugar in 1944, including infant foods, pharmaceuticals and penicillin, are more than 15 million pounds, exceeding 1943 production by at least 8 million pounds.

ALLIED FORCES DENTAL SOCIETY

The formation of an Allied Forces Dental Society, composed of leading dental surgeons of the Allied Nations, was recently reported by the American Dental Association. The society was formed for the purpose of pooling ideas to better the health of the fighting forces and to further postwar dental science, and more than 650 dental surgeons of the Royal Navy, Royal Air Force and American, British and Canadian armies have been admitted to membership in the society. Major Richard H. Carnahan of Texas, Capt. Philip S. Brackett of Massachusetts, Lieut. Comdr. E. S. Boden of Ohio and the help of British dental officials organized the new society, which was formed in London. Internationally known dental surgeons give lectures at the society's monthly meetings on latest methods of treatment.

ORGANIZATION SECTION

ANNUAL CONGRESS ON MEDICAL EDUCATION AND LICENSURE

Fortieth Annual Meeting, Held in Chicago, Feb. 14 and 15, 1944

(Concluded from p. 935)

THE FEDERATION OF STATE MEDICAL BOARDS

FEBRUARY 14—EVENING

FEDERATION DINNER

Licensure Trends and Medicine

ALPHONSE M. SCHWITALLA, S.J., St. Louis: The two chief categories of functions which are recognized to be the functions of the state boards, namely (a) the evaluation of professional competence of the physician and (b) the police power to debar from practice a physician proved to be unworthy, have in the past been differentially affected by social change. Hence it may be expected that they will be differentially affected by future social change. Of the two, the first group of functions, evaluation, is probably the more important for safeguarding the profession's integrity; the second is probably more important for securing the social protection of the people of which the state board is the guarantor. In the days that lie ahead the state boards will face intensified and greatly extended problems. Despite the adjustments which have been made in most states accepting a chronologically accelerated curriculum and accepting the recent recommendations of the Procurement and Assignment Service at the time when the 9-9-9 plan was introduced, there can be little doubt that numerous questions will arise concerning both the institutions from which students are graduating from this accelerated program and the particular qualifications of the individual applicant for license. There are still sufficient differences in the legal requirements for the practice of medicine to give rise to threatened increasing difficulties in reciprocity. To this problem there might be added the related problem of the foreign medical graduate. Then there stares us in the face as a seemingly inescapable menace the great problem of osteopathy. Despite the vigilance of the state boards there can be little doubt that cultism has gained ground in the last few years, and even though the responsibility for that growth cannot be laid at the door of the state board, nevertheless it is a state board problem that is growing in magnitude and in intensity. Then there is the question of the administration of examination methods for the purpose of determining the professional qualifications of the professional licensee, a question which on the surface is merely a matter of administrative policy but which is extremely far reaching in its professional implications. The objectives of the examination, standards of medical practice, the determination of procedures, all these and related questions are involved in any change of policy with reference to the method of examination. The state boards have accomplished much. They are face to face with much more. As medicine moves onward and upward the state boards too will have to enlarge their horizons and aspire to still higher heights of responsibility.

FEBRUARY 15—MORNING

DR. ADAM P. LEIGHTON, Portland, Maine, Presiding

ACCELERATED MEDICAL TRAINING AND RELATED LICENSURE IMPLICATIONS

Premedical Training

DR. VICTOR JOHNSON, Chicago: Acceleration in medical schools involves no basic changes except the elimination of the long summer vacations. Curricular changes are minimal, and no significant increase in weekly work by the student is required.

The premedical curriculum has been shortened by greatly increasing the daily and weekly assignments as well as by eliminating long vacations. The results of this experiment in concentrated premedical education will be watched with interest by all who are concerned about the long years of training required for the professions, especially medicine. A reduction in this time, somewhere between the beginning of grammar school and the internship, would be desirable if it could be effected without impairment of the quality of the product.

A second feature of the Army and Navy programs is a standardization of the premedical curriculum, with little time for elective work. While this might help to elevate standards in some of the weaker participating schools and may be convenient to administer, it is not desirable as an educational principle to be retained.

A third experiment—a major one—is the attempt to select students for the study of medicine at an earlier academic period than in peacetime. It will be important to know whether such early selection will be successful.

Certain features of the selection program are highly undesirable. Bilateral selection by the school and the student has not been incorporated into the plan. Committees of medical student deans select the students for the study of medicine, but these committees or the schools or the students may not determine which student shall attend which school. Although this is apparently an administrative necessity, it must be recognized as educationally unsound.

A fourth innovation in wartime premedical training is one which may prove to be even more far reaching in its consequences than the ones already mentioned. The Army and Navy programs entirely eliminate the economic requirement for the study of medicine. Under the Army and Navy programs, ability to pay for an education has nothing to do with the selection of those to be educated. A serious study should be made of this obvious but revolutionary principle, to determine whether an entirely new source of brain power is being tapped.

It should be possible to develop an educational program involving four years of general education in the humanities, social and natural sciences, commencing with the third year of high school and continuing until a student is about 18 or 19 years old. This could be followed by a program of five calendar years of the study of medicine in an integrated curriculum incorporating the preclinical laboratory sciences and the study of man in health and disease. Graduation with the M.D. degree would then occur at 23 or 24 years of age instead of at 26 or 27. Licensing bodies must continue to adjust themselves to changes or arbitrarily limit the extent to which medical education shall progress.

The Accelerated Program in Medicine

DR. E. M. MACEWEN, Iowa City: The accelerated program was accepted with many misgivings as a war emergency measure because there was no other method by which the production of doctors could be increased without seriously lowering medical educational standards. The chief criticisms that have been directed against the program are (1) that medical standards were being lowered, (2) that the war would be over before any appreciable number of doctors would be made available, (3) that the health of the medical students was endangered and (4) that the student would have no time for contemplation and digestion of new material.

It may be concluded that the accelerated program is meeting the condition for which it was adopted. It is definitely adding to the production of doctors. The financial worries of more than 80 per cent of the students have been solved. Their health should not be endangered more than under prewar conditions. The curriculum has not been shortened; in fact, it has been lengthened in many schools. Therefore in agreement with the statement of Johnson, the conclusion must be drawn that the

accelerated program "per se need not reduce the standards of medical education"; that if certain other conditions can be met, a modified accelerated program deserves serious consideration in the permanent postwar plans.

Up to the present all the students admitted to our schools have been selected by the faculties of the respective colleges. With the exception of the present freshman class, all the students have met the regular prewar admission standards of the particular school they entered. Many of the members of the freshman classes and at least 80 per cent of all new admissions for the duration will present only the reduced emergency premedical training. After Jan. 1, 1945 they will have had only the concentrated military premedical courses. Many of these courses will be taken in very large classes with minimal personal instruction and under very difficult study conditions. What effect this regimented program will have on the quality of our future classes only time will tell. The fact that most of these students will have no choice of schools and that the schools will have no direct voice in the selection of their students may materially change the type of the student body. Whether this change will be for better or for worse remains to be seen. The doctrine expressed at the beginning of this paper makes us skeptical. On the other hand some excellent young men who normally, because of financial difficulties, would not go beyond high school may now have the opportunity for a professional training.

Despite all these handicaps the faculties of our approved medical colleges will continue to demand quality work from all their students. That a uniform is not a protection against academic failure has been amply demonstrated during the past year.

Effect of the Accelerated Program on Hospital Internships

DR. JEAN A. CURRAN, Brooklyn: Reduction of all internships to nine months duration appears to have resulted at present in generally lowered educational standards and further accentuation of intern shortages. But perhaps it is a bit early to estimate the full impact of the accelerated curriculum and the abbreviated internship schedule on the final quality of medical product that will be delivered to the country during the war and the postwar years. From all sides there appears to be uniform agreement that the nine months internship, either rotating, mixed or straight, is inadequate as an educational experience. The arbitrary reduction of all internships to the length of an academic year has merely accentuated a long term development. Therefore the rationing instituted last autumn by the Procurement and Assignment Service must be viewed as merely a palliative and not a curative measure; and more fundamental remedies must be sought. After the conclusion of hostilities there will probably be considerable demand for residency opportunities by men returning from military service, for which preparations must be made. At the same time we may anticipate a steadily widening gap between the increasing number of internships annually made available and the number of graduates from our schools to fill them. Even if all hospitals are able to attain a satisfactory educational level and lengthen their internships to two years, I doubt very much if supply and demand can be balanced. The answer, so far as hospitals are concerned, would appear to be in the provision of a greatly increased number of mixed residencies on a salaried basis, similar in complexion to senior internships but of longer duration and shading off into part time and then voluntary arrangements. This would give valuable preparation for men intending to enter general practice and at the same time would provide the necessary house staff coverage.

But all this is in the future. As we try to face the present situation as realistically as possible, every effort must be made to use the personnel now available as effectively and efficiently as possible. As never before, it is essential that each new group of interns be given thorough orientation in their duties when they begin service. Through the use of "streamlined" procedure books, better teamwork among administrators, medical staffs, nurses, social workers and technicians, provision of more stenographic or clerical assistance and the elimination of every

unnecessary frill of "extra paper work" or extraneous duties, perhaps we may expect results as remarkable as those of the Kaiser shipyards. From painful necessity and through definition of new objectives in this changing social order, we may reach an attainment very sorely needed, namely a new vision and a spirit to insure its accomplishment.

While all of our resources at the present time are being devoted to an all out military effort, it would seem absolutely necessary that we plan as well for the postwar educational needs of our hospitals if we are going to avoid a prolonged medical depression.

Medical Licensure Aspects of Accelerated Medical Training

DR. J. EARL MCINTYRE, Lansing, Mich.: Much confusion now exists in the process of legalizing the practice of medicine by the new crop of graduates of the medical schools under the accelerated programs of education, including internship and those coming in by reciprocal indorsement. In states having basic science laws or inelastic statutory licensure requirements, serious situations have arisen. The Surgeons General and the Procurement and Assignment Service have formulated the 9-9-9 plan, and its adoption by some hospital associations has been announced in many states where either statutory requirements or provisions in basic science acts make it impossible for examining boards to correlate any convenient plan for the prompt examination and licensure of graduates, interns and those seeking license by interstate reciprocal indorsement.

Many states having statutory minimum educational requirements have remedied the situation by adopting amendments giving the state examining and licensing boards authority to modify such requirements and thus go along with the plan for acceleration of medical curriculum and for shorter internship training. Examination schedules and administrative processes were promptly adjusted in line with the new semester periods of the medical schools. We are confronted, however, in many states, as in Michigan, with the provisions of the basic science law which prohibit admission to examination or licensure by indorsement and which prohibit the practice of medicine by any one who does not hold a certificate from the State Basic Science Board, unless exempt by college matriculation prior to a certain date fixed by the statute.

The examining boards are asked to admit men to examination or licensure by interstate reciprocal indorsement without having first obtained the required basic science certificate. The examining boards are also asked to permit men to serve as residents or to practice medicine in hospitals under various classifications until the next medical or basic science examination without having first obtained medical licensure and, in many cases, the required basic science certificate. This the boards cannot do. They cannot by act or acquiescence issue any dispensation to any person to practice medicine in any capacity until such person obtains a license to practice medicine. Where the statute provides that they must first obtain a basic science certificate before being admitted to examination or before being licensed by interstate reciprocal indorsement, the board is powerless and can neither legally admit them to examination nor issue them a license by reciprocity, neither permit nor acquiesce in their serving as resident physicians or otherwise practicing medicine in any hospital or elsewhere in the state until the required certificate is first obtained.

Hospitals in many cases admit men to residencies without inquiring as to whether they are legally qualified under both medical acts or basic science laws to practice, believing that legal requirements as to examinations, licenses or certificates will soon be fulfilled. They then clamor for dispensation, and the doctors involved present most stirring accounts of the predicament in which they now find themselves.

The shortening of internship periods in states having statutory internship period requirements must be by a change in such statute, or an amendment. Where there are no such statutory requirements as to internship, the boards in the several states have yielded to the request of the military and shortened the internship period requirement by virtue of their rule making power.

There is another legal aspect of this whole problem on which I might briefly touch. It is a question of deferments. There is considerable ill feeling which has been aroused in individuals criticizing the military in taking able and legally qualified men into the service and deferring the unfit for further training. We in Michigan have found many cases in which men were deferred who were graduates of a C school and not eligible for licensure and of men who were deferred for further so-called internship training in hospitals which are not approved for internship training and who therefore never could be licensed to practice medicine in Michigan. The Office of Procurement and Assignment or any other federal agency or official has no authority to confer on any one the right to serve as a resident physician or to authorize the practice of medicine under any hospital classification who does not hold a medical license or a basic science certificate where required for the practice of medicine. The military may place these men in military service and the Office of Procurement and Assignment may so assign them, but they cannot assign them to civilian practice or to civilian hospitals.

I urged two years ago that some action be taken by the several states to establish uniformity of standards and requirements so that more uniform reciprocity may obtain between the several states. There is now little uniformity in basic science law requirements. Many men otherwise eligible not holding basic science certificates from another state are prevented from accepting hospital appointments or entering civilian practice for the reason that the basic science boards of the two states have technical bars to reciprocity.

FEBRUARY 15—AFTERNOON

The New Nebraska Medical Practice Act

DR. GEORGE W. COVEY, Lincoln, Neb.: The examinations for licensure in Nebraska are conducted, under the new law, by a board of five members instead of the old three member board. Section 7 of L. B. No. 139, amending section 71-305 of the compiled statutes of 1929, also provides that two of its members shall be officials or members of the instructional staff of a class A medical school. Furthermore, the terms of the members are staggered and any one member may remain on the board through only two consecutive terms. Section 20 relates to the requirements for admission to examination to practice medicine and surgery. Part of these requirements need some explanation or comment. Number 2 is as follows: "Present to the Department of Health a certificate of ability in anatomy, physiology, chemistry, bacteriology, pathology and hygiene issued by the Board of Basic Sciences." The Board of Basic Sciences has waived the examination in these subjects in certain instances, but only after examination of the papers of the applicants who have passed similar examinations in other states. Our Basic Science Board thus reserves the right to determine for itself that the applicant has had a comparable examination and that, in the opinion of the Nebraska board, he has made a passing grade. The final item in section 21 reads as follows: "An osteopathic school or college, fulfilling all the foregoing requirements, shall not be refused standing as an accredited medical school because it may also specialize in giving instruction according to any special system of healing." This section also includes the provision . . . that such minimum standards shall apply equally to all accredited schools." It places the entire responsibility for recommending schools for accreditation on the Board of Examiners in Medicine and Surgery.

Any school of osteopathy which can become accredited under the provisions of L. B. No. 139 is actually a so-called class A medical school and "osteopathic" in name only. Such a provision in the Nebraska law actually places the osteopathic school in its proper category. It is either teaching medicine and surgery according to accepted standards or it is teaching osteopathy. If it falls in the former category it will eventually cease to call itself osteopathic and its graduates will be doctors of medicine; if in the latter, they will remain osteopaths according to the accepted definition and will not seek to extend their practice beyond their lawful field. If similar laws were in operation throughout the nation, one can easily visualize the ease

with which many problems arising in relation to these two professions could be solved.

Many osteopaths had been practicing medicine and surgery in Nebraska prior to the Supreme Court decision which defined their scope of practice under the old law. This decision was so clear that all of those who had been practicing illegally were compelled to return to osteopathy. The effect was, however, to cause a redoubled effort on the part of the osteopaths to get legislation passed which would give them all the rights of physicians.

One examination has been given since the new bill became law. Twenty-one osteopaths took the examination under the provisions of this section. Of this number six passed and fifteen failed. There were seventy-nine doctors of medicine who took this same examination. Of these, all passed. It appears that a very small percentage of the osteopaths who fall under this provision will be licensed; that, if our present basic science law remains unchanged, a few new ones will become licensed to practice osteopathy and, if their schools become good enough to permit their being accredited, they will be doctors of medicine rather than osteopaths and thus the controversies may be ended.

The combination of a good basic science law with this medical practice act will in all probability lead to several results: In the first place, the over-all quality of medical practice should be improved. Whereas a few osteopaths may achieve the right to practice medicine and surgery, the rank and file of these cultists who are not qualified will be effectively prevented from so doing. Those who gain this right will be at least as well qualified as many of the practitioners who have the degree of doctor of medicine. There will be no opportunity for those who are not so licensed to practice lawfully any healing art excepting that defined by the Supreme Court decision of 1941. If similar laws are adopted elsewhere, the tendency will be for osteopathic schools to become class A medical schools and for osteopathy excepting for its intrinsic value as a form of physical therapy to die. We believe we shall be relieved of the necessity for constantly opposing legislation designed to undo our laws relating to medical practice. In other words, we hope that the menace of poorly qualified osteopaths and chiropractors attempting to come into the practice of medicine through the side entrance will have been effectually neutralized in Nebraska.

In conclusion, I should like to leave with you a thought which has presented itself to me and to others. Could the quality of medical practice be further elevated by an addition to our practice acts requiring that every licensee shall take an examination in medicine and surgery periodically to show that he continues to be qualified to practice his profession? This would eliminate the few who, after graduation, are no longer interested in further education and relieve us of the necessity for constantly apologizing for some members of our own profession.

Medical Legislation

J. W. HOLLOWAY JR., Chicago: Some time ago the requirements for acceptance in the Medical Corps of the Army were modified to admit, under specified conditions, graduates of non-accredited medical schools. Shortly thereafter there came to me an inquiry asking if service in the Medical Corps of the Army by such a graduate would qualify him for licensure in a state in which normally he could not qualify but in which the medical practice act contained an exemption in favor of former members of the Medical Corps of the Army. My answer was in the negative. While a number of states do relieve from the examination requirement applicants who have served in the Medical Corps of the Army, the matter of granting licenses to such applicants is usually left with the discretion of the licensing agency and is generally coupled with the requirement that the applicant must have graduated from an accredited medical school. Service in the Medical Corps of the Army, therefore, is not the open sesame to medical licensure as my correspondent implied. I myself do not feel that service in the Army or Navy Medical Corps should ipso facto qualify a physician for state licensure. The school of graduation is important, of course. So also is the quality of service rendered by the physician while in the Army or Navy, for some have been given honorable discharges for professional incompetence, for inadaptability and for other reasons that may or may not have a bearing

on qualification for licensure. Yet it does seem that the physician returning to civilian life deserves special consideration in the matter of licensure. He should not be penalized for answering the call of his country in her need.

Federal Funds for Relocation of Physicians

Early last October the President by special message asked the Congress to appropriate \$1,000,000 to be used by the Public Health Service to supply medical and dental care in critical areas. It was contemplated that the Public Health Service would use this appropriation to supply the needed care in one of two ways: (1) assign its own personnel to such areas to treat the civilian sick or (2) induce private practitioners of medicine and dentistry to move into the areas by paying them \$250 a month for a period of three months plus moving expenses. In event that the Public Health Service sent its own personnel into the areas to treat the civilian sick, it was proposed that these medical officers should charge for their services according to a fee schedule jointly formulated by the state department of health and the United States Public Health Service. The fees collected were to be turned over to the state department of

health to pay expenses incurred in rendering the care, such as office expense. If at the end of the year there remained any surplus, that surplus was to be covered in the Treasury of the United States. As enacted, the law provides \$200,000 instead of the \$1,000,000 initially requested, does not authorize the Public Health Service to assign its own personnel to critical areas, requires the requesting community to contribute 25 per cent of the cost and specifically provides that the relocated physician or dentist must obtain a license to practice in the state to which he moves.

While under this federal program the application for the services of a physician must be approved by the state health department, while the availability of physicians for relocation must be determined by the State Procurement and Assignment Service chairman, and while the financial arrangements will be made with the physician by the United States Public Health Service, the state licensing board will be the agency to determine the qualifications of the physician to practice in the state to which he is relocated. That determination must be made, of course, in compliance with state licensure laws.

U. S. PUBLIC HEALTH SERVICE TO STUDY BLUE CROSS PLANS

At the midwinter conference of plans for providing medical service, held in Chicago in February, it was voted to approve a study to be made by the U. S. Public Health Service of various Blue Cross hospital service plans. Following is a statement of the purposes, procedure and scope of the proposed study:

I. PURPOSE OF STUDY

The need for adequate health service to the people of America makes it desirable that the U. S. Public Health Service have an informed opinion of the present and potential usefulness of existing methods of distributing medical and hospital care.

The U. S. Public Health Service is interested in making a study to determine how well the Blue Cross Plans are now serving and may best serve public needs. Blue Cross Plans also are interested in learning how they may be made more effective. This study has been proposed in the public interest and its purpose is to appraise the advantages and limitations of Blue Cross Plans, which have enrolled thirteen million subscribers throughout the United States.

The board of trustees of the American Hospital Association and the Hospital Service Plan Commission have endorsed this study and have recommended that all Blue Cross Plans cooperate with the U. S. Public Health Service.

II. PROCEDURES OF STUDY

The study will include conferences with the directors and staffs of representative plans and, in cooperation with the plan directors, conferences with representatives of the hospitals, the medical profession and the general public in the community.

III. SCOPE OF STUDY

The study will include all aspects necessary for an understanding of the plans as individual entities and of the Blue Cross movement as a whole. This will cover the history, growth, subscription rates and benefits, contracts with hospitals, legal status, enrolment policies and problems, financial status, utilization experience and relations with hospitals, the medical profession and the general public. It will also include data as regards interplan relationships and the American Hospital Association approval program.

DOCTORS AT WAR

Radio broadcasts of Doctors at War by the American Medical Association in cooperation with the National Broadcasting Company and the Medical Department of the United States Army and the United States Navy are on the air each Saturday at 4:30 p. m. Eastern war time (3:30 Central war time, 2:30 Mountain war time and 1:30 Pacific war time).

The titles and guest speakers for the next three programs are as follows:

April 1. "White Reaper."

Speaker, Kendall Emerson, M.D., Managing Director, National Tuberculosis Association, New York.

April 8. "Men with New Faces."

Speaker, Major General D. N. W. Grant, M. C., A. U. S., Air Surgeon, A. A. F., Washington, D. C.

April 15. "Decks Aflame."

Speaker, Capt. French Moair (MC), U.S.N., Washington, D. C.

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Changes in Status.—S. 662 has been passed by the House to authorize pensions for certain physically or mentally helpless children. The purpose of this bill is to remove an inequality in existing law for the benefit of a small number of helpless children of the veterans of the Civil War, the Indian wars, the Spanish-American War, including the Philippine Insurrection and the Boxer Rebellion, and the Regular Establishment whose service was prior to April 21, 1898. S. 1767 has passed the Senate, contemplating the enactment of the "Servicemen's Aid Act of 1944." A subcommittee of the House Committee on Interstate and Foreign Commerce has concluded hearings on H. R. 3379, a bill to codify the laws relating to the Public Health Service. H. R. 4371 has been reported to the House, proposing an annual appropriation of \$5,000,000 to enable the Department of Labor to cooperate with state agencies adminis-

tering labor laws in establishing and maintaining safe and proper working conditions in industry and in the preparation, promulgation and enforcement of regulations to control industrial health hazards.

Bills Introduced.—S. 1808, introduced by Senator Johnson, Colorado, provides for temporary appointment as officers in the Army of the United States of members of the Army Nurse Corps, female persons having the necessary qualifications for appointment in such corps, female dietetic and physical therapy personnel of the Medical Department of the Army, exclusive of students and apprentices, and female persons having the necessary qualifications for appointment in such department as female dietetic or physical therapy personnel. S. 1809, introduced by Senator Johnson of Colorado for Senator Reynolds, North Carolina, proposes to remove the limitation on the right to command of officers of the Dental Corps of the Army, the

existing limitation restricting such officers to command in the Dental Corps. S. 1813, introduced by Senator Wagner of New York for himself and for Senator George of Georgia and Senator Clark of Missouri, proposes to amend title II of the Social Security Act so as to give insurance credits under the federal old age and survivors' insurance provisions of that act for military service. S. 1778, introduced by Senator Langer, North Dakota, is similar in objective to the preceding bill. H. R. 4447, introduced by Representative Allen, Louisiana, proposes the appropriation of an amount not in excess of \$5,000,000 to construct in or near Gum Springs, La., a 1,000 bed patient veterans' hospital for the diagnosis, care and treatment of neuropsychiatric disabilities. H. R. 4448, introduced by Representative Domengeaux, Louisiana, proposes to provide for free government inspection of sea food. H. R. 4418, introduced by Representative Walter, Pennsylvania, provides that persons who are otherwise qualified, but who have physical defects which will not interfere with the performance of general or special duties to which they may be assigned, may be issued appointments in the Naval and Marine Corps Reserve and ordered to active duty.

STATE MEDICAL LEGISLATION

Kentucky

Bill Enacted.—H. 259 was approved by the governor, March 18, so amending the narcotic drug act as to define narcotic drugs to include isonipecaïne.

Mississippi

Bills Introduced.—Senate Concurrent Resolution 32 and House Concurrent Resolution 41 propose to provide for the appointment of a special committee to consider the desirability of enacting a workmen's compensation act in the state and to report its conclusions to the 1946 session of the legislature. S. 384 proposes to authorize the board of supervisors of Harrison County to provide medical and hospital treatment and care for any resident of the county who, because of indigency, cannot obtain the care required.

North Dakota

Bill Introduced.—S. 5-X proposes to authorize the state health department in cooperation with the University of North

Dakota to obtain blood from donors in the state, to purchase equipment necessary for processing that blood, to process the blood, and to furnish blood plasma so processed free of charge to the people of the state.

Rhode Island

Bill Introduced.—H. 834 proposes to permit practicing assistant pharmacists who have passed examinations identical with the examinations given for registered pharmacists and who have been employed as duly qualified registered assistant pharmacists for ten or more years to conduct or manage pharmacies.

Virginia

Bills Enacted.—The following bills have been approved by the governor: H. 29, repealing the existing medical practice act and enacting an entire new act, which, among other things, gives representation on the board of medical examiners to the homeopaths, osteopaths, chiropractors and naturopaths. All applicants for licenses to practice any form of the healing art must pass examinations to be given by the board in anatomy, histology, pathology, physiology, bacteriology or microbiology, biochemistry, diagnosis, sanitation and hygiene; S. 165, to require every state agency authorized to conduct examinations of applicants for licenses to practice any profession to file a copy of each examination within a period of ten days after it is given with the secretary of the commonwealth, who must preserve it for at least two years as a public record accessible to any person; S. 170, to amend the narcotic drug act so as to define a narcotic drug as to include isonipecaïne; S. 219, so to amend the laws relating to venereal diseases as to require public health officers to investigate all cases of lymphogranuloma inguinale or granuloma inguinale as well as syphilis, gonorrhea and chancroid, to authorize health officers to require persons suspected of being infected with any of those diseases to submit to examination and to make it a misdemeanor for any person found infected with any of those diseases to fail to take the treatment prescribed by a competent physician or to fail to continue treatment until cured; and S. 234, to prohibit the retail sale or distribution, except on the prescription of a doctor of medicine, dentist or veterinarian, of hormones or hormone drug preparations.

WOMAN'S AUXILIARY

Minnesota

The Goodhue County auxiliary and Nicollet-LeSueur counties made cancer dressings for Our Lady of Good Counsel Free Cancer Home in St. Paul.

The Hennepin County auxiliary recently gave its annual Silver Tea for Sarahurst rehabilitation home for patients from Glen Lake Sanatorium.

Mrs. F. S. McKinney, state president of Minnesota, was guest speaker at the November meeting of Washington County auxiliary.

Mississippi

The Gulfport unit of the Woman's Auxiliary of the Harrison-Stone-Hancock Counties Medical Society celebrated its twentieth anniversary recently at the home of the organizer, Mrs. D. K. Williams, with Dr. Emma Gay, a charter member, as co-hostess.

The Woman's Auxiliary of Clarksdale and Six Counties Medical Society had its semiannual meeting in November. Dr. E. LeRoy Wilkins, president of the state medical society, gave a talk on juvenile delinquency.

North Carolina

Mrs. Reuben McBrayer, president of the Hoke County auxiliary, has given an emergency medical kit in memory of her husband's father, Dr. L. B. McBrayer.

Pitt and Wayne County auxiliaries held meetings recently, and Wake County auxiliary held open house December 10 at the home of Dr. and Mrs. M. D. Hill for Wake County doctors and their wives.

Pennsylvania

Pennsylvania reported at the national board meeting that it had the largest number of *Hygeia* and *Bulletin* subscriptions. It is also working actively against the Wagner-Murray-Dingell bill.

Beaver County voted to give \$50 to the Passavant Home, \$50 to the Beaver County Tuberculosis Sanitarium, \$10 for a tuberculosis bond and \$5 to the Salvation Army.

Berks County auxiliary made surgical dressings in November and gave seventy-five garments to the Needlework Guild.

Cambria County auxiliary had a dinner in Johnstown recently.

Erie County auxiliary heard Dr. Martin M. Malinex of Brooklyn discuss "Congenital Heart Disease and Rheumatic Fever" at the Nurses Home at Hamot Hospital in Erie.

Lehigh County auxiliary held its annual reciprocity tea recently in Allentown. Congressman Charles Gerlach explained the Wagner-Murray-Dingell bill and pledged himself "to do all in his power to defeat the insidious and un-American provisions of the bill."

Philadelphia County, Montgomery County, Schuylkill County and Franklin County held interesting meetings recently. At a fashion show held by the Philadelphia County auxiliary \$600 was netted.

Westmoreland County auxiliary voted to contribute \$150 to the medical benevolence fund.

Medical News

(PHYSICIANS WILL CONFERR A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

CALIFORNIA

University News.—Dr. F. P. Ludueña, adjunct professor of pharmacology of the medical faculty of the University of Rosario, Argentina, has become assistant professor in the department of pharmacology of the Stanford University School of Medicine, San Francisco.

Pharmacists Arrested in Drug Sale.—More than 40 men, most of them pharmacists, have been arrested in connection with the sale of a drug to enable army draftees to evade induction, newspapers reported March 16. According to the report, state and army officials conferred on plans to halt the sale of the drug, which army men said causes apparent mental and physical unfitness for military service on the part of men taking it. Pharmacists arrested for its sale are being charged with dispensing it without a prescription, it is reported.

Dr. Lyttle Named Professor of Pediatrics.—Dr. John D. Lyttle, since 1921 a member of the faculty of Columbia University College of Physicians and Surgeons, New York, has been appointed professor of pediatrics at the University of Southern California School of Medicine, Los Angeles, and director of pediatrics of the Children's Hospital, effective April 1. Dr. Lyttle graduated at Cornell University Medical College, New York, in 1916. He joined Columbia in 1921 as an instructor, subsequently serving as associate and assistant clinical professor of pediatrics.

Physicians Needed.—The Los Angeles County Civil Service Commission announces that applications for resident physicians (radiology) are now being accepted. Applications are to fill positions in the Los Angeles County Hospital. Eligible physicians are those who are 21 to 55 years of age, graduates of an approved medical school, who have completed at least nine months' internship in an approved hospital. Applications will also be accepted from interns prior to the completion of their internship. There will be no written examination. Applications must be filed on or before April 15. Additional information may be obtained from the Los Angeles County Civil Service Commission, Room 102, Hall of Records, Los Angeles 12.

INDIANA

Society News.—The La Porte County Medical Society was addressed at La Porte, February 17, by Rolla N. Harger, Ph.D., Indianapolis, on "Domestic and Industrial Poisonings."

—At a meeting of the St. Joseph County Medical Society in South Bend recently Dr. Louis N. Katz, Chicago, spoke on the "Principles in the Diagnosis and Treatment of Peripheral Vascular Diseases."

Industrial Health Conference.—The Indiana State Medical Association will conduct its second industrial health conference at the Indiana University School of Medicine, Indianapolis, April 19-20. Among the speakers on the program will be:

- Dr. Jacob T. Oliphant, Farmersburg, Obligations of the State Medical Association in the Training of Industrial Physicians.
- Dr. Willis D. Gatch, Indianapolis, Obligations of the University in the Training of Industrial Physicians.
- Dr. Roscoe L. Sensenich, South Bend, Postwar Industrial Health Problems.
- Dr. Stewart L. Rankin, Charlestown, Medical Records and Record Keeping in Industry.
- Samuel M. Peck, senior surgeon, U. S. Public Health Service Reserve, Occupational Aene.
- Dr. Sumner L. S. Koch, Chicago, Treatment of Hand Injuries.
- Dr. John H. Foulger, Wilmington, Del., Preventive Medicine in Industry.
- Dr. Victor G. Heiser, New York, Value of Industrial Medical Services in Industry.
- Dr. Dudley A. Irwin, Pittsburgh, Prevention and Treatment of Silicosis with Aluminum.
- Dr. Kenneth E. Markuson, Lansing, Mich., A New Technic in Drawing Blood for Serodiagnostic Tests: Use of the Hemospast.
- Dr. Oscar A. Sander, Milwaukee, Lung Changes in Electric Arc Welders.
- Dr. Verne K. Harvey, Washington, D. C., Present Day Employment of Physically Handicapped Under Federal Civil Service.
- Dr. Harold A. Vonachen, Peoria, Ill., Community Organization for Rehabilitation and Recemployment.

The program will include a symposium on "Rehabilitation and Employment of the Handicapped Veteran," with Col. Anthony J. Lanza, M. C., A. U. S., as the moderator.

KENTUCKY

Medical Students Examine Domestic Employees.—Students of the University of Louisville School of Medicine are examining domestic employees in a program for the examination of workers conducted by the medical school and partly financed by the Louisville Tuberculosis Association. According to the *Bulletin* of the National Tuberculosis Association, blood pressure and blood samples for the Kahn test are taken and the Snellen vision test made. An examination of the eye, ear, nose and throat and dental examination, urinalysis, cervical smears and blood analyses are included in the work done by the students. Chest fluoroscopy is made under the supervision of a physician in charge of the clinic, and the results are recorded on the patient's history blank. On completion of the work, physicians in charge of the clinic go over the results.

MASSACHUSETTS

New Dean of Boston University.—Dr. Charles F. Branch, professor of pathology, Boston University School of Medicine, has been appointed dean of the school to succeed Dr. Bennett F. Avery, who resigned to become director general of public health of Iran. Dr. Branch, a graduate of the University of Vermont College of Medicine, Burlington, in 1923, has been a member of the teaching staff of the school for eighteen years, serving as professor of pathology since 1932.

Final Commencement of Harvard Dental School.—On March 23, fifteen army students, sixteen navy and seven civilian students graduated at Harvard Dental School, the last graduates of the oldest university dental school in the United States. On March 31, responsibility for dental education and research at Harvard was assumed by the Harvard School of Dental Medicine, which at the end of four years will confer the degree of D.M.D. on its graduates (*THE JOURNAL*, May 15, 1943, p. 187).

Warren Triennial Prize Awarded.—The Warren Triennial Prize, awarded through the Massachusetts General Hospital, Boston, has been presented for 1943 to Dr. David G. Cogan, V. Everett Kinsey, Ph.D., and Erwin O. Hirsch, B.A., for their essay entitled "Physiological Studies on the Cornea." An essay entitled "Studies on Traumatic Shock" by Dr. Everett I. Evans, Richmond, Va., was awarded honorable mention in the competition. The prize was founded by the late Dr. J. Mason Warren in memory of his father, Dr. John C. Warren, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation considered worthy of a premium on some subject in physiology, surgery or pathologic anatomy, the arbiters being the executive committee of the Massachusetts General Hospital. The amount of the prize for 1943 was \$500.

MICHIGAN

Changes in Health Officers.—Dr. John K. Altland, Hastings, was to resume his position as director of the Barry County Health Department on March 16, newspapers reported. Dr. Altland has been serving with the coast guard but has now been placed on the inactive list.

Physician Sentenced as Spy.—Dr. Fred W. Thomas, Detroit, on March 16 was sentenced to sixteen years in federal prison following his conviction of conspiracy to violate the wartime espionage act. The sentence was passed by federal Judge Edward J. Moinet, after the conviction of Dr. Thomas two weeks previously by a federal court jury. Newspapers stated that the physician was accused of supplying espionage information on war production and troop movements and ingredients for the manufacture of invisible ink to Miss Grace Buchanan-Dineen, described by the federal bureau of investigation as leader of the espionage ring.

Plasma Program to Be Expanded.—During a recent special session of the legislature, \$250,000 was appropriated to augment the plasma program conducted by the state department of health. The project includes the enlarging of facilities in the state laboratories. New construction is to provide an additional 3,900 square feet of floor space which, according to the state department of health, will permit the production of four times the amount of plasma produced heretofore. The plasma program was launched in the state last September and has now been extended to thirty-three Michigan communities, the service including the establishment of plasma reserves in local hospitals. Physicians are supplied with the plasma, free of charge, for the treatment of civilian patients. One traveling clinic, a physician and four nurses, is also a part of the program, and present plans call for the commissioning of two more units.

MINNESOTA

Dr. Herrell Honored by Chamber of Commerce.—Dr. Wallace E. Herrell, assistant professor of medicine, University of Minnesota Graduate School, Rochester, was recently presented with the distinguished service key of the Rochester Junior Chamber of Commerce for "outstanding service in 1943." The report indicated that the award went to Dr. Herrell for his work on penicillin.

MISSOURI

Raymond McIntyre Enters Military Service.—Mr. Raymond McIntyre, St. Louis, executive secretary of the Missouri State Medical Association, has been granted a leave of absence from the association to accept a commission in the U. S. Navy as lieutenant (jg).

Physician Provides Bequest for Hospital.—Dr. Caleb A. Ritter, who at the time of his death January 31 was reported to be resident in the Trinity Lutheran Hospital, Kansas City, left a trust fund to the hospital to be used for the maternity department and to be known as the Dr. C. A. Ritter bequest.

Symposium on Degenerative Diseases.—The research unit of the St. Louis City Infirmary and the Washington University School of Medicine, St. Louis, cooperated in a symposium at the infirmary, March 24, on degenerative diseases. Among the speakers participating were:

- Dr. Irvine H. Page, Indianapolis, Arteriosclerosis and Lipid Metabolism.
- Dr. Lester R. Dragstedt, Chicago, The Role of the Pancreas in Arteriosclerosis.
- Dr. Edward J. Stieglitz, Washington, D. C., Difficulties in Clinical Recognition of Degenerative Diseases.
- Dr. William J. Kerr, San Francisco, Correlation of Clinical Knowledge in the Treatment of Degenerative Diseases.

At a dinner session, the speakers included George Reeves Throop, LL.D., chancellor, Washington University, Dr. Frank Fremont-Smith, medical director, Josiah Macy Jr. Foundation, New York, and Dr. William deB. MacNider, Kenan research professor of pharmacology, University of North Carolina School of Medicine, Chapel Hill, who spoke on "Age: Change and Adjustment."

NEW JERSEY

Hospital Receives Physician's Library.—The Nathan and Miriam Barnett Memorial Hospital, Paterson, has been presented with the library, medical and surgical supplies and office equipment of the late Dr. David H. Mendelsohn, who at the time of his death was attending surgeon at the hospital. According to the *Bulletin* of the Passaic County Medical Society, the library consisted of more than 200 textbooks and 5 bookcases. The equipment consisted of an operating table, autoclave, instruments, microscope and other articles. An oil painting of Dr. Mendelsohn, the work of Henry J. Wolff, was recently dedicated and hung in the solarium of the hospital.

State Medical Meeting.—The Medical Society of New Jersey will hold its annual meeting at the Hotel Claridge, Atlantic City, April 25-27, under the presidency of Dr. Ralph K. Hollinshead, Westville. One general session will be addressed Tuesday afternoon by Drs. Louis H. Bauer, Hempstead, N. Y., Walter H. Judd, Washington, D. C., and Robin C. Buerki, Philadelphia, on "Postwar Planning." "A Country Doctor in Washington" and "Postwar Medical Education" respectively. Another will be addressed Thursday morning by Mr. E. A. van Steenwyk, Philadelphia, on "Can Voluntary Health Insurance Meet the Need?" and Capt. Don S. Knowlton (MC), U. S. Naval Reserve, "The Marines Have Landed." At the banquet Wednesday evening, Dr. Samuel Emlen Stokes, Moorestown, will be toastmaster and Dr. James E. Paullin, Atlanta, President of the American Medical Association, will discuss "Place of the Physician in the Postwar World." Among other speakers on the program will be:

- Lieut. Col. Henry A. Christian, and Major Charles S. Morrow, M. R. C., Diagnosis of Cardiac Abnormalities Through the Use of Positional Electromyograms.
- Dr. Truman G. Schnabel, Philadelphia, Bronchiogenic Carcinoma.
- Dr. George Morris Piersol, Philadelphia, The Diagnosis of the Continued Fevers Commonly Encountered in General Practice.
- Dr. Martin E. Rehffuss, Philadelphia, Medical Treatment of Biliary Tract Disease.
- Dr. William O. Wuester Jr., Elizabeth, Cancer of the Lip and Skin.
- Dr. Benjamin W. Carey, Pearl River, N. Y., Newer Aspects of Chemotherapy.
- Dr. Murray H. Bass, New York, Lipoid Diseases.
- Dr. William H. Hahn, Newark, Role of Vitamins in Physiology of Vision.
- Dr. Richard D. Swain Jr., Newark, Oral and Ocular Manifestations of Head Trauma.
- Dr. Henry B. Orton, Newark, Infection of the Neck.
- Dr. Wilbur Emory Burnett, Philadelphia, Postoperative Care of the Gallbladder Patient.
- Major Champ Lyons, M. C., A. U. S., Treatment of Burns, Shock and Hypoproteinemia.

- Dr. Alfred Meurlin, East Orange, Analysis of One Hundred Puerperal Deaths in Essex County.
- Dr. Hammell P. Shipp, Camden, The Abortion Problem.
- Dr. Julius Levy, Newark, The Federal Aid Program.
- Dr. Lyman Burnham, Englewood, The Rh Factor.
- Dr. Alan F. Guttmacher, Baltimore, Social Problems of Obstetrics and Gynecology.
- Dr. Sigurd W. Johnsen, Passaic, Common Disorders of the Digestive Tract.
- Dr. George T. Pack, New York, Metabolic Disturbances Associated with Cancers of the Gastrointestinal Tract.
- Capt. J. Edward Berk, M. R. C., Gastrointestinal Problems in the Army.
- Dr. Julius Gerendasy, Elizabeth, Diagnostic Pitfalls in Proctology.

NEW YORK

Personal.—Dr. Albert J. Colton, Buffalo, who invented the card index system bearing his name, will observe his eightieth birthday, April 17.—The New Rochelle Medical Society gave a dinner on February 15 in honor of Dr. Frank B. Littlewood, who recently completed fifty years in the practice of medicine.

Graduate Lectures.—A series of lectures on general medicine opened March 30 for the medical staff of Memorial Hospital of Greene County, Catskill. Dr. Laird S. Van Dyck, New York, delivered the first lecture, on "Diagnosis and Treatment of Common Skin Diseases." Others in the series will be:

- Dr. David K. Miller, Buffalo, What Do We Know About Vitamins?
- April 27.
- Dr. Wallace B. Hamby, Buffalo, The Diagnosis and Treatment of Head Injuries, May 25.
- Dr. A. Wilbur Duryee, New York, Circulatory Disturbances in the Extremities, June 29.

Dr. Byron P. Stookey, New York, addressed the Broome and Tioga County Medical societies in Binghamton, March 14, on "Low Back Pain."

New York City

Pharmacy and Public Health.—On April 10 the New York Branch of the American Pharmaceutical Association will meet in Keating Hall on the Fordham University Campus under the auspices of the university's college of pharmacy. The theme of the meeting will be "Pharmacy and Public Health" and the speakers will include:

- Mary Grace, Ph.G., New York, The Hospital Pharmacist's Role in Public Health.
- Carl R. Addinall, Ph.D., Rahway, N. J., The Pharmaceutical Manufacturer's Contribution to Public Health and the War Effort.
- Dr. Walter Clarke, New York, The Pharmacist's Part in the Social Hygiene Program.
- Ivor Griffith, Sc.D., Philadelphia, The Retail Pharmacist's Part in Public Health and the War Effort.

Program to Reduce Home Accidents.—A series of ten teacher training lectures on home safety opened in various health centers on March 20 under the auspices of the city department of health, the Greater New York Safety Council and the National Safety Council. The lectures will continue weekly until June 9 and will serve as a training course for health department personnel to instruct others in home safety. During the course all students will study and report causes of home accidents. The project is financed by the National Safety Council in the expectation that it will develop a pattern of effective home accident prevention methods which subsequently may be used throughout the United States. The lectures, with visual demonstrations of home accident causes and methods of prevention, have been developed, and a teaching staff of about 40 recruited, organized and trained by the Greater New York Safety Council. Classroom and teaching facilities are provided by the city department of health.

OHIO

Tri-State Medical Meeting.—The seventy-first annual meeting of the Northern Tri-State Medical Association will be held at the Commodore Perry Hotel, Toledo, April 11. The meeting will be opened with addresses by Drs. Paul M. Holmes, president, Toledo Academy of Medicine, and E. Benjamin Gillette, Toledo, president of the Northern Tri-State Medical Association. Other speakers will include:

- Dr. Gordon B. Myers, Detroit, Chemotherapy.
- Dr. Robert A. Hettig, Ann Arbor, Mich., Postwar Medical Problems Relative to Tropical Diseases.
- Drs. Karl D. Figley, Toledo, Milton B. Cohen, Cleveland, and Stanley W. Insley, Detroit, The Management of the Asthmatic.
- Dr. Henry C. Hesselstine, Chicago, Caudal Anesthesia.
- Dr. Marion A. Blankenhorn, Cincinnati, Diagnosis and Treatment of Medical Shock.
- Dr. Nathan S. Davis, Chicago, The Role of Biochemistry in the Etiology and Treatment of Cardiovascular Renal Disease.
- Dr. Walter E. Dandy, Baltimore, Diagnosis and Treatment of Ruptured Intervertebral Disks.
- Dr. Wallace E. Herrell, Rochester, Minn., Penicillin.

The Northern Tri-State Medical Association is composed of the states of Indiana, Michigan and Ohio.

SOUTH CAROLINA

State Medical Meeting.—The annual session of the South Carolina Medical Association will be held at the Columbia Hotel, Columbia, April 11-12, under the presidency of Dr. William Atmar Smith, Charleston. A banquet session will be addressed by Dr. Harry S. Mustard, professor of public health practice and director of the De Lamar Institute of Public Health of Columbia University College of Physicians and Surgeons, New York. Among other speakers on the program will be:

- Dr. Mylnor W. Beach, Charleston, Trend of Immunization in Present Day Pediatrics.
- Dr. William H. Kelley, Charleston, Specific Chemotherapy in Bacterial Infections.
- Dr. James C. McLeod, Florence, The Use of Sulfonamides in Surgery.
- Dr. Edgar A. Hines, Jr., Rochester, Minn., The Prevention and Treatment of Thrombosis and Embolism.
- Dr. Roderick MacDonald, Rock Hill, Headache from an Eye, Ear, Nose and Throat Standpoint.
- Dr. Joseph D. Guess, Greenville, Practical Obstetrics.
- Dr. Roger G. Doughty, Columbia, The Problem of Ruptured Intervertebral Disks.
- Dr. Oscar Z. Culler, Orangeburg, The Treatment of Diabetic Coma.
- Dr. Thomas B. Sprunt, Baltimore, The Management of Thyrotoxicosis.

TENNESSEE

State Medical Meeting.—The Tennessee State Medical Association will hold its one hundred and tenth annual meeting in the Noel Hotel, Nashville, April 11-13, under the presidency of Dr. Oval N. Bryan, Nashville. According to the preliminary program, the meeting will open with an evening session to be addressed by Dr. Bryan, Dr. James E. Paullin, Atlanta, President of the American Medical Association, and Brig. Gen. Hugh J. Morgan, consultant to the Surgeon General of the army. Among the guest speakers will be:

- Dr. Frank E. Whitacre, Sylvania, Ohio, Some Complications of Obstetrics as Seen in China.
- Dr. Louis A. Buie, Rochester, Minn., A Colored Motion Picture of Normal and Abnormal Conditions in the Terminal Portion of the Colon, with Comments.
- Dr. Austin E. Smith, Secretary, Council on Pharmacy and Chemistry, American Medical Association, Chicago, Drugs on the Market.
- Dr. Carl M. Peterson, Secretary, Council on Industrial Health, American Medical Association, Chicago, Industry Needs the Physician.
- Dr. J. R. Bromwell Branch, Macon, Ga., Benign Obstructive Lesions in the Right Lower Quadrant.
- Dr. Charles H. Mann Jr., New York, Practical Aspects of the Management of Lymphogranuloma Venereum.

The program will conclude with a symposium on the venereal disease problem by Drs. Herman Spitz, Nashville; J. Logan Morgan, Memphis; Rudolph H. Kampmeier, Nashville; Emmett R. Hall, Memphis, and Dr. Mann.

TEXAS

Changes in Health Officers.—Dr. Thomas P. Andrews has resigned as health officer of Brownsville. Dr. Charles A. Wyatt, Marshall, was recently appointed health officer of Harrison County.

New Lectureship at University of Texas.—An annual lectureship under the auspices of the Phi Beta Pi medical fraternity has been established at the University of Texas Medical Branch, Galveston. The first lecture was given on March 25 by Theophilus S. Painter, Ph.D., professor of zoology at the University of Texas, Austin, entitled "A Cytologist Looks Forward."

Pediatric Program.—Dr. Arild E. Hansen, professor of pediatrics, University of Texas Medical Branch, Galveston, and director of the school's child health program, is arranging a pediatric conference at the school, April 7-8, with a group of special speakers, to survey current pediatric problems in the Southwest. On this occasion the first of a series of lectures on pediatrics, sponsored by the William Buchanan Foundation of Texarkana, will be given by Dr. Irvine McQuarrie, professor of pediatrics, University of Minnesota Medical School, Minneapolis.

UTAH

Industrial Hygiene Physician Goes to Washington.—Dr. John L. Jones, Salt Lake City, has resigned as director of the division of industrial hygiene, Utah State Board of Health, to become chief of the medical services of the Washington State Health Department, Seattle, effective March 1. A graduate of Harvard Medical School and the Harvard School of Public Health, Dr. Jones in 1935 served as state health commissioner of Utah. From 1939 to 1941 he was given leave of absence to develop the state's first industrial hygiene program and carry out studies in cooperation with the U. S. Public Health Service. He became director of the new division of industrial hygiene in 1941.

WEST VIRGINIA

Former Health Commissioner Named Medical Director of Compensation Fund.—Dr. William T. Henshaw, Charleston, has been named by Charles L. Heaberlin, state compensation commissioner, as acting medical director for the Workmen's Compensation Fund to succeed Dr. Ernst F. Gott, who will resume private practice in Charleston. Dr. Henshaw served for several years as state health commissioner and has been medical director for the Dravo Construction Company since 1933. Work on the Hinton dam, which is being constructed by the Dravo Corporation, has been discontinued temporarily because of the shortage of vital materials.

Forum on Tropical Diseases.—A feature of the annual meeting of the West Virginia State Health Conference on May 1-2 at Charleston will be a forum on tropical diseases. Various aspects of the diseases to be discussed include clinical diagnosis and therapeutics, laboratory and field control, and etiology and epidemiology. All sessions of the conference, which is a joint meeting of the West Virginia Public Health Association and Health Officers Conference, will be held at the Daniel Boone Hotel. In addition to the forum on tropical diseases there will be the following speakers:

- Lucius F. Badger, surgeon, U. S. Public Health Service, Newer Methods of Communicable Disease Control.
- Dr. Philip E. Blackerby, Louisville, Ky., Rural Health.
- Hortense Hilbert, New York, Nursing.
- Dr. Arthur J. Lesser, Washington, D. C., Emergency Maternal and Infant Care Program.
- Dr. Udo J. Wile, Ann Arbor, Mich., Venereal Disease Control.

WISCONSIN

Examination for Medical Examiners.—The Milwaukee County Civil Service Commission announces an examination for the position of medical examiner, applications to be filed on or before April 5. The initial salary will be about \$390 a month, and acceptance will be determined by an evaluation of training and experience plus an oral interview. Qualified citizens of the United States are eligible. Applicants must be graduates of an approved school and be eligible for a license to practice medicine in Wisconsin. They must have not less than three years of specialized training, exclusive of internship, in an accredited institution or department of pathology, the training to have included not less than one year of various phases of clinical pathology and not less than two years in the department of pathologic anatomy. Additional information may be obtained from the Milwaukee County Civil Service Commission, Room 206, Courthouse, Milwaukee.

Sessions on Industrial Health.—The State Medical Society of Wisconsin, in cooperation with the industrial hygiene unit of the state board of health, has planned a series of afternoon and early evening conferences to be held in six industrialized areas of the state:

- April 12, Kenosha, Elks Club.
- April 19, Manitowoc, Manitowoc Hotel.
- April 25, Oshkosh, Hotel Raulf.
- May 2, Green Bay, Hotel Northland.
- May 16, Janesville, Y. M. C. A.
- May 18, Wausau, Hotel Wausau.

Two teams have been chosen: one from Madison to handle the Oshkosh, Wausau and Janesville meetings; the other from Milwaukee to lecture at Kenosha, Manitowoc and Green Bay. Members of the Madison team are Drs. Henry L. Greene, Chester M. Kurtz, Vincent W. Koch, Helen A. Dickie, Erwin R. Schmidt, Albert R. Tormey and Garrett A. Cooper. Members of the Milwaukee group are Drs. Chester C. Schneider, Elwood W. Mason, Millard Tufts, Arthur A. Schaefer, Joseph M. King, Simpson M. Markson and Oscar A. Sander. Included among the topics of discussion will be:

- Treatment of Sprains and Strains.
- Cardiac and Hypertension in Industry.
- Industrial Disease of the Lungs.
- Treatment of Burns.
- Treatment of Injuries to the Hands and Feet.
- Prevention and Treatment of Industrial Dermato Health Hazard in Welding.

Among others, Dr. Paul A. Brehm, Madison, supervisor of the industrial hygiene unit of the state board of health, will speak on the importance of postwar planning in relation to the rehabilitation of war veterans in industry.

HAWAII

Dr. McNeil Resigns as Mental Hygiene Director.—Dr. Edwin E. McNeil, Honolulu, who left Hawaii last September on vacation and a six months leave of absence, has resigned as director of the bureau of mental hygiene, of the Territory of Hawaii Board of Health, effective February 15. Dr. William M. Shanahan, Honolulu, has been acting director of the bureau.

GENERAL

National Negro Health Week.—The week beginning April 2 has been designated National Negro Health Week to promote the health and well-being of Negroes. A national observance will be carried out under the auspices of the U. S. Public Health Service.

Wartime Public Health Conference.—The American Public Health Association announces that its second wartime public health conference and its seventy-third annual business meeting will be held in the Pennsylvania Hotel, New York, October 3-5. Meetings of related organizations will take place on October 2. The scientific program will be devoted to wartime emergency matters as they affect public health.

Medals Awarded for Orthopedic Exhibits.—At the recent annual meeting of the American Academy of Orthopaedic Surgeons three gold medals were awarded, one to Dr. James E. M. Thomson, Lincoln, Neb., for his exhibit showing originality of presentation and research problems entitled "Local Shock Influence of Novocain Sympathetic Block." Another medal for scientific importance and information went to Dr. William T. Green, Boston, for his exhibit on "Skeletal Manifestations of Neurofibromatosis" and a medal for clinical value to Col. John L. Gallagher, M. C., U. S. Army, for his exhibit on "Compression Therapy Dressings." Dr. Guy W. Leadbetter, Washington, D. C., was chosen president-elect of the academy and Dr. E. Bishop Mumford, Indianapolis, was inducted into the presidency. Other officers include Drs. H. Earle Conwell, Birmingham, Ala., vice president; Fremont A. Chandler, Chicago, treasurer, and Myron O. Henry, Minneapolis, secretary. The academy will hold its next annual meeting at the Palmer House, Chicago, Jan. 21-24, 1945.

Panel Named to Assist in Placing of Veterans in Industry.—The Industrial Hygiene Foundation has announced that a panel of five members will function as an advisory board for the placement of veterans in industry. The panel consists of Dr. Clarence D. Selby, medical consultant, General Motors Corporation, Detroit; Col. John H. Andrews, executive officer, Reemployment Division, National Selective Service System, Washington, D. C.; Dr. Harley L. Krieger, medical director, Ford Motor Company, Detroit; A. A. Hendrix, personnel director, Eastern Aircraft Division, General Motors Corporation, Linden, N. J., and I. Dent Jenkins, personnel manager, Harrison Radiator Division, General Motors Corporation, Lockport, N. Y. The action was taken after the release of the comprehensive report by the Industrial Hygiene Foundation on "Putting the Disabled Veteran Back to Work." It is stated that the five man panel will serve the foundation's membership and industry generally as an unofficial vehicle for the exchange of practical experience and information.

Award to Encourage Writing of Medical Books for Laymen.—W. W. Norton & Company has established a new literary award to be known as the Norton Award to consist of \$3,500 and "offered to encourage the writing of books on medicine and the medical profession for the layman." According to an announcement the publishers, whose list is characterized by some authoritative books on medical subjects, feel that medical men, like other scientific workers, write for one another for the most part, and the layman is consequently too often forced to resort to nonprofessional popularizers. In announcing this award they have in view the need for books on various aspects of medical science, written by professional workers in the medical field in such a way as to interest the general reading public. The subject matter to be considered may be autobiography, biography, history of any phase of medicine, exposition of medical science or of medical theory. Complete information and entry blank for this award may be obtained by addressing the Norton Award, W. W. Norton & Company, Inc., 70 Fifth Avenue, New York 11. Final date for delivery of manuscripts is Dec. 31, 1944.

Chest Physicians Hold Regional Meetings.—The North Midwest Regional District of the American College of Chest Physicians will sponsor a meeting during the annual session of the Minnesota State Medical Association in Rochester, April 15. Among the speakers will be:

- Dr. Sidney A. Slater, Worthington, Minn., Practical Points in the Diagnosis of Pulmonary Tuberculosis.
- Dr. John F. Allen, Omaha, Development of Therapy in Tuberculosis During the Last Twenty-Five Years.
- Dr. Horton C. Hinshaw, Rochester, Present Status of Chemotherapy in Tuberculosis.
- Dr. Karl A. Danielson, Litchfield, Minn., "All Out" Tuberculosis Control by the Medical Profession.
- Dr. William L. Meyer, Sanator, S. D., Sarcoidosis.
- Dr. Leonard W. Moody, Bayfield, Wis., Case Reports.
- Dr. J. Winthrop Peabody, Washington, D. C., Transitory, Migratory Pulmonary Infiltrations Associated with Eosinophilia.

The New Jersey chapter will meet during the session of the Medical Society of New Jersey at the Hotel Claridge,

Atlantic City, April 26. The Ohio chapter will hold a luncheon session at the Deshler-Wallick Hotel, Columbus, May 3, in connection with the annual meeting of the Ohio State Medical Association.

LATIN AMERICA

Health Activities in Latin America.—The presence of high yielding Ecuadorian sources of quinine has been reported by William C. Steere, Ph.D., botanist attached to the U. S. Foreign Economic Administration mission in Quito, Ecuador. The high yielding plant is known as *Cinchona pitayensis*, or yellow bark, and was known previously only in Colombia. According to the Office of the Coordinator of Inter-American Affairs, wild bark is being brought out of the Ecuadorian forests, nurseries are developing plantations and factories in Quito are processing the bark for shipment to the United States.

Health Education.—A new motion picture on prevention of blindness entitled "Eyes for Tomorrow," produced by the Emerson Yorke Studio for the National Society for the Prevention of Blindness, will be released throughout Latin America under the auspices of the Office of the Coordinator of Inter-American Affairs. This version will be slightly altered to the original release in the United States and will have Spanish and Portuguese sound tracks. The film deals with the importance of antepartum care as a means of reducing the amount of blindness caused by syphilis and gonorrhea, the conservation of vision among school children, the use of sight-saving classes for children with seriously defective vision, the necessity for regular eye examinations, methods of treating glaucoma and trachoma and the eye hazards of industry.—Fifteen minute broadcasts four times a week of instruction in public health nursing were started recently in Bolivia.

Texas Physician Honored.—Dr. James L. Rentfro, Brownsville, was guest of honor at a banquet given by the Matamoros Medical Association, Tamaulipas, Mexico, in recognition of his work among the Latin American people on both sides of the Rio Grande. Dr. Roberto Perez M., president of the Matamoros Medical Association, presided at the dinner, which was attended by members of the profession from Texas and Mexico. Dr. Rentfro was presented with a certificate of merit signed by all members of the Matamoros Medical Association. Nelson R. Park, American consul, in a communication to the Department of State said that it is believed to be the first occasion on which the Matamoros doctors have honored a physician of Brownsville.

Medical Care for Sisal Workers.—Through an arrangement with Haiti's special health service, workers on the largest sisal plantation in the Western Hemisphere, known as the La Plantation Dauphin and located in Haiti, are being given special care under the Inter-American health and sanitation program. Physicians and engineers have been assigned to the project, which includes drainage of malarial swamps, improvement of water supply, establishment of small medical dispensaries and construction of additional housing facilities.

Personal.—Dr. Pablo Mirizzi, professor of clinical surgery of the University of Cordoba, Argentina, was recently presented by the University of Brazil with the degree of professor honoris causa. Special ceremonies were held at the National Faculty of Medicine at Rio de Janeiro.—Dr. Antonio Augusto de Almeida was recently elected president of the Medical Association of the Penido Burnier Institute, Campinas, São Paulo, Brazil.—Dr. José A. Hernández Ibáñez was chosen president of the Sociedad Cubana de Urología.—Dr. Alberto Recio-Forn, Havana, has been appointed minister of health of Cuba.

Tuberculosis Control.—Dr. Joseph S. Spoto, traveling representative of the Pan American Sanitary Bureau, reports in the *Bulletin* of the National Tuberculosis Association that an agreement has been reached by the federal health department of Mexico, the chief of party of Mexico, Office of the Coordinator of Inter-American Affairs and the Pan American Sanitary Bureau, to initiate a tuberculosis control program on the northern border of Mexico.

Deaths in Other Countries

Dr. William W. C. Topley, professor of bacteriology and immunology in the University of London and director of the division of bacteriology and immunology, London School of Hygiene and Tropical Medicine from 1927 to 1941, died January 21, aged 57. Dr. Topley devoted himself to the investigation of the factors which influence the spread of bacterial infection, and he invented and used entirely new methods for the study of epidemics in a population of laboratory mice. He was one of the first to use experimental methods in the study of epidemics, and he became an authority on the subject.

Canadian Neurologic Hospital in Britain

Establishment of a Canadian neurologic hospital for the troops in Britain was described at the Neurologic Section of the Royal Society of Medicine by Lieut. Col. J. C. Richardson. A new organization for dealing with neurologic patients was hailed as an important advance by the experts who took part in the discussion. The hospital was opened in 1940 with 200 beds for the treatment of head injuries. Needs not originally foreseen caused a steady expansion until in July 1943 the hospital had 600 beds, of which 150 were devoted to plastic surgery and 250 to neuropsychiatric maladies. The vast majority of the patients were Canadian soldiers and a considerable number Canadian airmen, but there were a few civilians and British service patients. Mild or severe mental disorders comprised 70 per cent of the cases, neurologic disorders without permanent mental disturbance 19 per cent and general medical disorders 8 per cent. The largest group (1,625 of 4,436 cases in three years) comprised psychoneuroses, about half the number being anxiety states. Patients with psychopathic personality numbered 646, psychoses 507 (chiefly schizophrenia 355 cases) and mental defectives 306. Of the cases of neurologic disease (828) the largest number (275) were cases of epilepsy and the next most numerous neurosyphilis (117).

The reported experience of the hospital was that neurology, psychiatry and neurosurgery, when planned as different components of one broad field of medical practice, offered the advantage of cooperative handling from the points of view of clinical investigation, diagnosis, treatment and postgraduate training. Such organization helped to break down the artificial barrier between the neurologist and the psychiatrist. Neuropsychiatry, it was pointed out, had been called on to play a much larger part in the selection of troops and allocation of personnel, including choice of candidates for commissions, than was originally anticipated. It was felt that the experience of this military neuropsychiatric division would be of lasting value in planning improvements in teaching hospitals and in directing attention to the psychiatric aspect of somatic illness.

In the discussion, Brig. Gen. George Riddoch, a British neurologist, said that this Canadian experiment would have an immense influence in planning for the future. The term which best described the hospital organization, he said, was "common sense." Sir Henry Tidy praised the liaison between neurology and psychiatry and stated that it would be to the mutual advantage of psychiatry and general medicine if they were as closely in touch.

Proposed Clinic for Advice in Infertile Marriages

The Social Biology Board of the British Social Hygiene Council proposes to establish in London a special clinic at which both partners of an infertile marriage can obtain expert advice. This clinic would be run on the same lines as the voluntary hospitals. Specialists would give their services voluntarily. An appeal is being made for the necessary funds. It is estimated that \$25,000 will be needed before the clinic can be equipped and started, but it is believed that by charging fees on a sliding scale to those who can afford them, the clinic would become self supporting within a comparatively short time.

The Social Biology Board has agreed to promote this undertaking under the supervision of its finance committee, provided

the public will contribute the funds necessary for establishing the clinic. It is intended that the clinic should be open to all patients, general practitioners, hospitals and other institutions desiring to make use of its services. It would be equipped with all the apparatus necessary for diagnosis and would be prepared either to supply treatment or to guide the treatment given by the patient's private doctor. In previous letters the concern felt at the approaching decline of our population has been shown. Means for opposing this tendency have been suggested, and this new clinic is evidently designed as a contribution to that end. The serious view taken by some as to the population decline is illustrated by the speech of W. R. Inge, formerly dean of St. Paul's Cathedral and a well known publicist. At a commemorative luncheon of the Ruskin Society he said that our period as a great and wealthy nation had come to an end. We would gradually slide back, he said, into the equivalent of preindustrial England, with a population of 20 million, mainly agriculturists and small tradesmen in the towns. But Dr. Inge's pronouncements have earned for him the sobriquet of "the gloomy dean," and his forecast is regarded by most observers here as an exaggeration of a real danger.

Campaign to Prevent Introduction of Malaria into Pacific Islands

A new campaign against the *Anopheles* mosquito which carries the malaria parasite is to be launched in the Southwest Pacific. If malaria should be introduced into the islands there, which at present are free from infection, it might cause as many casualties as the war against Japan. The scheme is to be financed under the colonial development and welfare act of 1940, and an initial grant of \$325,000 to cover three years' work has been made for the purpose. The *Anopheles* mosquito has hitherto been unknown in Fiji, Tonga, the Cook islands, the Loyalty islands, New Caledonia, the Gilbert and Ellice islands and Samoa. On the other hand, malaria is widely distributed in the islands to the west of Fiji. Since the outbreak of war the establishment of large garrisons and the increase of air and sea traffic between the islands has greatly increased the danger of introducing malaria into islands hitherto free from it.

A start has been made with entomologic surveys near shores and ports and reconnaissance surveys of all potential breeding grounds. Normal anti-mosquito work will be intensified and danger places will be cleared, drained and oiled when necessary. At the same time an engineer will prepare a program for mosquito control on a long term basis.

The Production of Penicillin

The discovery of penicillin was made by Prof. Alexander Fleming, assistant director of inoculation in the Research Department of St. Mary's Hospital. Its use was developed by Prof. H. W. Florey. It is now being produced in large quantities in this country and the United States. Professor Florey has gone to Russia to direct its production there. Directions for its production have been flown to China.

Up to the present time penicillin has been manufactured only by biologic, as distinct from chemical, methods. The Therapeutic Research Corporation of Great Britain, which was established in 1941, has organized a pooling of research among the principal British drug houses. Subsequently the Medical Research Council and the Committee on Medical Research in the United States arranged for the regular exchange of information between teams of workers in the universities and industrial laboratories and other institutions on both sides of the Atlantic.

The activities of the institutions and undertakings concerned are coordinated with the various interested ministers and service departments in the General Penicillin Committee of the Ministry

of Supply. There is nothing of the nature of a monopoly in this organization, but there is full mobilization of the appropriate skill and talent of Britain and the United States for speeding the solution of the problem of manufacture of the supplies of penicillin which are so vitally needed.

BUENOS AIRES

(From Our Regular Correspondent)

Feb. 19, 1944.

Medical Aid to Victims of San Juan Earthquake

San Juan, the capital of San Juan province, was demolished by an earthquake in January. More than 5,000 persons were injured. The government, the national department of public health and the medical profession gave immediate medical care to the victims and established the necessary hygienic measures to prevent epidemics. The physicians of Cordoba and Mendoza came immediately to San Juan. Dr. Eugenio A. Galli, head of the national department of public health, with a large group of public health physicians, left Buenos Aires as soon as the department was informed of the disaster and reached San Juan within twenty hours. The wounded were evacuated in airplanes to Mendoza province. Vaccination against epidemic diseases was administered. Large groups of medical delegations from the various states of Argentina as well as from Chile, Uruguay and Paraguay reached San Juan soon after the earthquake. Offerings of any kind of help were made by the American government and the American Red Cross and notes of condolence were sent to the victims' families.

Venereal Diseases in Buenos Aires

Dr. Osvaldo D. Dodero of Buenos Aires reviewed statistics of various hospitals in Buenos Aires on the frequency of syphilis before and after establishment of the laws of 1936 and 1937 for abolition of prostitution in Argentina. The figures in the accompanying table were included in the report.

Patients with Venereal Disease Treated in Buenos Aires

	1932	1937	1938	1939	1940	1941	1942	1943
At 16 public health dispensaries for men:								
Syphilis.....	3,048	1,015	1,102	782	802	716	739	396
Gonorrhea.....	8,929	5,948	5,009	4,525	4,307	4,286	4,556	2,938
Other venereal diseases	3,742	2,992	3,164	3,163	3,223	3,762	4,362	2,517
At 7 dispensaries in private hospitals:								
Syphilis.....	2,681	2,343	1,827	1,713	1,582	1,517	1,397	650
Gonorrhea.....	6,016	4,301	3,953	3,045	3,314	4,729	5,551	2,671
Other venereal diseases	3,974	6,345	7,613	6,519	6,014	7,171	7,531	3,591

The figures for 1943 were for the six months from January to June. The figures given reflect the good results of the law against prostitution. According to Dr. Dodero, syphilis has recently increased in some provinces in which enforcement of the law was neglected. Sexual delinquency has also diminished during the last five years, it is reported.

Pulmonary Emphysema

Drs. Egidio S. Mazzei and Jorge M. Remolar of the Instituto de Investigaciones of the Academia de Medicina of Buenos Aires have recently published a book on the clinical, x-ray and therapeutic aspects of pulmonary emphysema. The clinical symptoms, x-ray signs and bronchographic findings in functional (or reversible) anatomic and bullous pulmonary emphysema caused by bronchial obstruction are discussed. The conception of symptomatic emphysema in various diseases and the causal role of the valvular mechanism in the production of the disease by intrabronchial cancer, tuberculosis and other diseases of the respiratory tract are explained. Bullous emphysema is the last stage of obstructive emphysema with valvular mechanisms. The

differential diagnosis between this type of pulmonary emphysema and other diseases which simulate it is discussed. In the field of experimental pulmonary emphysema the conceptions of Paine of Minneapolis concerning the importance of the valvular mechanism during expiration are confirmed. Various chapters deal with the clinical symptoms of respiratory, circulatory and nervous complications and with the diagnosis, prognosis and therapy of the various forms of the disease.

Brief News

Members of the Academia Nacional de Medicina of Buenos Aires recently held a literary reunion in honor of Dr. Emile Sergeant, who recently died.

Dr. Leo Eloesser of the surgical clinic of the University of San Francisco recently returned home after having delivered exchange lectures in Argentina.

Dr. Germán Hugo Dickmann, head of the department of neurosurgery of the Rawson Hospital of Buenos Aires, recently left Argentina for the United States, at the invitation of Dr. Walter E. Dandy of the Johns Hopkins Hospital, Baltimore.

A donation was made by the Argentine public on Christmas day by sale of the so-called stamps of Navidad. The money thus collected is used in work against tuberculosis. In the 1942 collection \$12,500 was obtained by this means.

Literary festivities and social entertainment on January 4 celebrated the fiftieth anniversary of *La semana médica* of Buenos Aires. A special illustrated issue of this journal is in preparation as part of the celebration.

Literary festivities were held on Dec. 17, 1943 by the Society of the History of Medicine, a branch of the Asociación Médica Argentina, in homage to Robert Koch on the one hundredth anniversary of his birth. Drs. Pablo Osvaldo Wolff and Ramon Pardal made addresses in his memory.

Literary festivities are being prepared for Oct. 16, 1946 in honor of William T. G. Morton to celebrate the centennial of surgical anesthesia.

Dr. Egidio S. Mazzei was appointed president of the Sociedad de Medicina Interna, which is a branch of the Asociación Médica Argentina.

Deaths

Dr. Carlos Mainini, 64 years of age, who was a well known specialist on tuberculosis and the president of the Asociación Médica Argentina from 1936 to 1942.—Dr. Juan Raul Goyena, gastroenterologist, professor of clinical medicine of the Faculty of Medicine of Buenos Aires.—Dr. Desiderio Fernando Davel of Buenos Aires, founder in 1886 of the Pasteur Laboratory in Buenos Aires, who taught in Argentina the methods for prevention and therapy of hydrophobia.

Aerial Accident

A grave aerial accident occurred at the Mendoza airdrome involving a Chilean airplane which had been lent to Argentina by the Chilean government. Several physicians of both countries were among those killed in the accident.

Marriages

FRANCIS WILLOUGHBY TRAYNOR, Cumberland, Md., to Miss May Agnes Skinner of Charleston, S. C., in Baltimore, February 28.

JOSEPH COOKE ORMAN, Nashville, Tenn., to Miss Margaret Josephine Griesbeck of Memphis, February 21.

FAY ASHTON CARMINES, Odd, Va., to Miss Lillie Weeks Burns of Goldsboro, N. C., March 4.

JOSEPH J. GELLER, Elizabeth, N. J., to Miss Anna Marie O'Keefe in New York, December 21.

JOSEPH H. LUCINIAN to Mrs. B. Edna Roberts, both of Miami, Fla., December 25.

Ellis Saunders Allen Jr. ♂ Louisville, Ky.; University of Louisville School of Medicine, 1934; fellow of the American College of Surgeons; commissioned a first lieutenant in the medical corps, Army of the United States, May 5, 1942 and began extended active duty on May 15, 1942 at O'Reilly General Hospital, Springfield, Mo.; later promoted to captain; discharged on Sept. 9, 1943 because of physical disqualification; served on the staffs of the Kentucky Baptist Hospital, Methodist Deaconess Hospital and St. Anthony's Hospital; died in St. Vincent Hospital, Jacksonville, Fla., January 13, aged 35, of tumor of the brain.

James Mortimer Hoffman ✱ Pensacola, Fla.; Tulane University of Louisiana School of Medicine, New Orleans, 1920; member of the Southeastern Surgical Congress, the South Atlantic Association of Obstetricians and Gynecologists and the Radiological Society of North America, Inc.; fellow of the American College of Surgeons; past president and secretary of the Escambia County Medical Society; served as president of the staff of the Pensacola Maternity Home and also on the regular staff; on the staff of the Pensacola Hospital; died January 19, aged 43, of coronary thrombosis.

James W. Ames, Detroit; Howard University College of Medicine, Washington, D. C., 1894; formerly a member of the state legislature; for many years a member of the county board of supervisors and chief diagnostician for the city board of health; medical director of the Trinity Hospital; died January 31, aged 79, of coronary heart disease and essential vascular hypertension.

David Elmer Arnold, San Francisco; College of Physicians and Surgeons of Chicago, 1893; served during World War I; formerly associated with the U. S. Veterans Bureau; died January 5, aged 76, of carcinoma of the prostate.

Homer Moon Austin ✱ Columbus, Ohio; Medical College of Ohio, Cincinnati, 1902; served during World War I; at one time chief of the division of hygiene of the state department of health; formerly superintendent of the Licking County Tuberculosis Sanatorium, Newark, Ohio, and assistant superintendent of the Clark County Tuberculosis Hospital, Springfield; on the staff of the Columbus State Hospital; died January 20, aged 73, of coronary occlusion.

Frank F. Barthmaier, Philadelphia; Hahnemann Medical College and Hospital of Philadelphia, 1910; served during World War I; on the staffs of the Women's Homeopathic Hospital and the Hahnemann Hospital, where he died recently, aged 56, of hypertensive heart disease.

Daniel Hughes Bell, Tacoma, Wash.; University Medical College of Kansas City, Mo., 1903; member of the Washington State Medical Association and the Pacific Coast Oto-Ophthalmological Society; past president of the Puget Sound Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; at one time superintendent of schools at Amarillo, Texas; on the staff of St. Joseph's Hospital and on the surgical staff of Tacoma General Hospital, where he died recently, aged 72, of cerebral thrombosis.

Daniel L. Bevan, Le Roy, Pa.; College of Physicians and Surgeons, Baltimore, 1908; member of the Medical Society of the State of Pennsylvania; at one time on the staff of the Robert Packer Hospital, Sayre; on the staff of the Tioga County General Hospital, where he died January 26, aged 62.

Robert Henry Black, Blackford, Ky.; University of Louisville Medical Department, 1886; died January 11, aged 82, of pneumonia.

Franklin Virginius Boyd, Opelousas, La.; Medical Department of Tulane University of Louisiana, New Orleans, 1902; member of the Louisiana State Medical Society; director of St. Landry Parish health unit; formerly health officer of Lake Providence; past president of St. Landry Parish Medical Society; died January 30, aged 64, of cardiac dilatation.

Samuel S. Briggs, Nashville, Tenn.; Vanderbilt University School of Medicine, Nashville, 1889; for many years professor of anatomy at his alma mater; died January 28, aged 76, of heart disease.

Nathan Stephen Brody, Brooklyn; University and Bellevue Hospital Medical College, New York, 1924; member of the Medical Society of the State of New York; served on the staffs of the Crown Heights, Madison Park and Israel Zion hospitals; died in Miami Beach, Fla., in January, aged 43.

Fletcher Hastings Brooks ✱ Surgeon, Lieutenant Commander, U. S. Navy, retired, San Diego, Calif.; Baltimore Medical College, 1902; member of the Medical Association of Georgia; entered the U. S. Navy on July 22, 1905 and retired March 13, 1924; at one time director of the John D. Archbold Memorial Hospital, Thomasville, Ga.; died in the U. S. Naval Hospital January 27, aged 68, of carcinoma.

Howard D. Brothers, Agra, Kan.; Omaha Medical College, 1883; died recently, aged 83.

Elbridge L. Busby, Henderson, Ky.; Kentucky School of Medicine, Louisville, 1903; member of the Kentucky State Medical Association; at one time superintendent of the Central State Hospital, Lakeland, and the Western State Hospital, Hopkinsville; died in the Protestant Deaconess Hospital, Evansville, Ind., January 24, aged 65.

Alfred Cahn, Mannsville, N. Y.; Albert-Ludwigs-Universität Medizinische Fakultät, Freiburg, Baden, Germany, 1903; died January 17, aged 64.

James Phaon Caldwell, St. Paul; University of Minnesota College of Medicine and Surgery, Minneapolis, 1909; member of the Minnesota State Medical Association; on the staffs of St. Luke's Hospital, St. John's Hospital and the Midway Hospital, where he died January 20, aged 60, of lymphosarcoma.

Frank A. Cavanaugh, South Haven, Kan.; Eclectic Medical Institute, Cincinnati, 1894; member of the Kansas Medical Society; died in Toledo, Ohio, January 18, aged 83, of myocarditis.

Herbert Augustus Chase, Cambridge, Mass.; Boston University School of Medicine, 1876; at one time a vice president of the Wilsey Savings Bank of Boston; died January 27, aged 93, of myocarditis and bronchopneumonia.

Franklin Higby Church ✱ Salem, N. J.; Johns Hopkins University School of Medicine, Baltimore, 1906; for many years county physician; on the staff of the Salem County Memorial Hospital; chief clinician, Salem County Social Disease Clinic; at one time physician to an expedition to South America for the University of Pennsylvania; died January 24, aged 63, of diabetes mellitus.

Frederick S. Clapp, Middlefield, Ohio; Western Reserve University Medical Department, Cleveland, 1884; died in St. Luke's Hospital, Cleveland, January 1, aged 80, of uremia.

Constant Moreaux Colignon ✱ Muskegon, Mich.; Rush Medical College, Chicago, 1914; fellow of the American College of Surgeons; past president of the Muskegon County Medical Society; served overseas as a captain in the medical corps of the U. S. Army during World War I; on the surgical staff and vice chief of staff for many years, Mercy Hospital; on the surgical staff of the Hackley Hospital; organized and directed the medical department of Campbell, Wyant and Cannon Foundry Company; died January 21, aged 53.

Charles A. Crane, Corunna, Mich.; Detroit College of Medicine, 1891; member of the Michigan State Medical Society; past president of the Shiawassee County Medical Society; formerly coroner of Shiawassee County and chairman of the Shiawassee County Democratic Committee; served as county jail physician; on the staff of the Memorial Hospital, Owosso; died suddenly January 24, aged 78, of angina pectoris.

Alexandre d'Artun, Lawrence, Mass.; Université de Lausanne Faculté de Médecine, Switzerland, 1919; died in the Deaconess Hospital, Boston, January 25, aged 50, of bronchopneumonia, pulmonary metastatic sarcoma and osteochondrosarcoma of the right ileum.

John Joseph Egan, Gloucester, Mass.; Harvard Medical School, Boston, 1894; member of the Massachusetts Medical Society; died January 22, aged 73.

Clara S. Eirley, St. Petersburg, Fla.; Woman's Medical College of Baltimore, 1892; member of the Indiana State Medical Association and the American Psychiatric Association; specialist certified by the American Board of Psychiatry and Neurology, Inc.; served on the staff of the Logansport State Hospital, Logansport, Ind.; died January 30, aged 76, of myocardial degeneration.

Joseph Wilbur Ehmer, Crivitz, Wis.; Northwestern University Medical School, Chicago, 1900; died in Pembine recently, aged 77, of hypostatic pneumonia, cardiac failure and myocarditis.

Laszlo Joseph Endrey ✱ Cleveland; Magyar Királyi Pázmány Petrus Tudományegyetem Orvosi Fakultasa, Budapest, Hungary, 1913; on the staff of the Lutheran Hospital; found dead January 28, aged 55, of a self-inflicted bullet wound.

Edward Purdon Evans ✱ Milwaukee; Rush Medical College, Chicago, 1894; formerly professor of pediatrics at the Marquette University School of Medicine; for eighteen years medical examiner of the Equitable Life Assurance Society of the United States; served overseas during World War I; on the staff of the Misericordia Hospital; died January 31, aged 70, of coronary thrombosis and angina pectoris.

Arthur Ezra Falkenbury ✱ Whitehall, N. Y.; Albany (N. Y.) Medical College, 1896; past president of the Washington County Medical Society; on the staff of the Glens Falls Hospital, Glens Falls; formerly a member of the school board; died January 23, aged 78, of lobar pneumonia.

Joshua Harlan Fell, Canyon City, Ore.; Rush Medical College, Chicago, 1888; died January 16, aged 80, of arteriosclerosis.

Herbert Loring Frost, East Cleveland, Ohio; Homeopathic Hospital College, Cleveland, 1886; fellow of the American College of Surgeons; past president of the staff and

member of the visiting staff, Huron Road Hospital, where he died February 10, aged 83, of pneumonia and arteriosclerotic heart disease.

Jesse Franklin Goff, Lexington, Tenn.; Vanderbilt University School of Medicine, Nashville, 1916; member of the Tennessee State Medical Association; died January 11, aged 59.

Norborne Taliaferro Greer, Rockymount, Va.; University of Maryland School of Medicine, Baltimore, 1892; died January 25, aged 76.

Rufus Lynn Grier, Lumpkin, Ga.; Atlanta Medical College, 1893; died December 11, aged 74.

Max Gutman @ New York; University and Bellevue Hospital Medical College, New York, 1908; died in the Jewish Memorial Hospital January 29, aged 62, of heart disease.

George Herbert Hanson, Los Angeles; Bennett College of Eclectic Medicine and Surgery, Chicago, 1906; formerly mayor of Paisley, Ore.; died January 17, aged 66, of post-operative shock due to carcinoma of the bladder.

Roy Nolan Hare @ Jasper, Ala.; Vanderbilt University School of Medicine, Nashville, Tenn., 1925; past president of the Walker County Medical Society; member of the board of directors of the First National Bank of Jasper; chief of staff, Peoples Hospital; died in the Jefferson Hospital, Birmingham, January 25, aged 49, of heart disease.

Charles Meigs Harrison, Napoleon, Ohio; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1892; member of the Ohio State Medical Association; on the staff of the S. M. Heller Memorial Hospital; died January 31, aged 76, of angina pectoris.

Grant Summer Hicks, Tacoma, Wash.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1887; member of the Washington State Medical Association; died January 19, aged 78, of cerebral hemorrhage.

Walter Howard Hill, San Francisco; John A. Creighton Medical College, Omaha, 1913; on the staff of St. Luke's Hospital; died January 28, aged 55.

Blanca H. Hillman, Drexel Hill, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1905; at one time on the staff of the Woman's Hospital, Philadelphia; died in Nokomis, Fla., January 30, aged 67, of carcinoma of the pancreas and gallbladder, mitral stenosis and left ventricular failure.

Charles J. Hoban @ Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1886; on the staff of St. Agnes Hospital; died in the Doctor's Hospital January 30, aged 83, of pneumonia.

William Joseph Holton @ Plant City, Fla.; University of Georgia Medical Department, Augusta, 1911; served in the U. S. Army for three years in the Philippines just after the insurrection; died in the Veterans Administration Facility, Bay Pines, January 7, aged 60.

Edward Max Knecht @ Washington, D. C.; Harvard Medical School, Boston, 1937; diplomate of the National Board of Medical Examiners; commissioned a first lieutenant in the medical reserve corps of the U. S. Army on Sept. 26, 1940, later stationed at the Walter Reed General Hospital; dishonorably discharged on Nov. 8, 1941; died February 4, aged 34, of acute congestive heart disease.

James E. McConnell, Somerset, Colo.; Rush Medical College, Chicago, 1896; died in Delta recently, aged 74, of carcinoma of the prostate.

Charles H. Merrill, Detroit; University of Wooster Medical Department, Cleveland, 1905; a captain in the medical corps of the U. S. Army during World War I; served as a member of the tuberculosis division of the city board of health and the research division of Parke Davis & Company; died February 26, aged 64, of coronary thrombosis.

Melvin G. Paden, White Oaks, N. M.; Louisville (Ky.) Medical College, 1886; formerly health officer and druggist; died recently, aged 82, of pneumonia.

Lucy C. Waite Robinson, Denver; the Hahnemann Medical College and Hospital, Chicago, 1883; Harvey Medical College, Chicago, 1895; at one time on the staff of the Mary Thompson Hospital of Chicago for Women and Children; served as a delegate to the International Congress of Surgeons in Lisbon and Moscow; died recently, aged 83, of chronic myocarditis, concussion of brain and shock due to a fall.

O. Lee Schattensburg @ Honolulu, Hawaii; University of California Medical School, San Francisco, 1925; served as recording secretary and president of the Honolulu County Medical Society; consultant, maternal and infant welfare bureau of the board of health; on the staffs of Queen's, St. Francis and Kapiolani hospitals; died July 10, 1943, aged 48, of toxic myocarditis secondary to infected psoriasis.

Clayton Myron Spencer, Scottville, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1907; member of the Michigan State Medical Society; a lieutenant during World War I; formerly mayor of Scottville; served as a member of the board of education; member and past president of the Rotary Club; a director of the Scottville Savings Bank; died in the Paulina Stearns Hospital, Ludington, January 31, aged 65, of coronary thrombosis.

John Peter Toomey, Boston; Harvard Medical School, Boston, 1893; died recently, aged 73.

Henry Mitchell Waldren, Drayton, N. D.; Queen's University Faculty of Medicine, Kingston, Ont., Canada, 1898; member and past president of the North Dakota State Medical Association; formerly member and past president of the North Dakota State Board of Medical Examiners; fellow of the American College of Surgeons; medical director and owner of the Drayton Hospital; died in the University Hospital, Minneapolis, February 22, aged 68, of Hodgkin's disease.

Joseph Lonzo Wicks @ Evanston, Wyo.; Ohio Medical University, Columbus, 1898; past president of the Wyoming State Medical Society and of the Uinta County Medical Society; member of the House of Delegates of the American Medical Association session in 1905; county health officer; served as physician for the Bear River Coal Company and as member of the city council; a member of the Wyoming legislature in 1933 and 1935; since 1918 president of the Stockgrowers Bank of Evanston; died January 31, aged 73, of hypertensive heart disease.

Timothy Graham Williams, Rosehill, N. C.; George Washington University School of Medicine, Washington, D. C., 1911; served during World War I; died December 27, aged 56.

DIED WHILE IN MILITARY SERVICE

Edward Murray Fitzgerald, Pittsburgh; Georgetown University School of Medicine, Washington, D. C., 1936; member of the Medical Society of the State of Pennsylvania; commissioned a first lieutenant in the medical reserve corps of the U. S. Army June 7, 1936 and later promoted to captain; died at De Ridder, La., February 11, aged 34.

Albert Whitfield Hawkes, Cutchogue, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1935; member of the Medical Society of the State of New York; commissioned a major in the medical corps, Army of the United States, on Feb. 27, 1942 and attached to the 9th General Hospital, Fort Andrews, Mass.; died in the South Pacific area Dec. 17, 1943, aged 37, of typhus.

Raymond Barnard Miles @ Brooklyn; Yale University School of Medicine, New Haven, Conn., 1924; fellow of the American College of Surgeons; served as instructor in the department of surgery at the Long Island College of Medicine; at one time assistant to the chief medical examiner of New York; formerly an associate staff surgeon at the Brooklyn Hospital; served during World War I; began extended active duty Nov. 3, 1942 as a major in the medical reserve corps, U. S. Army, attached to the 79th General Hospital, Camp White, Medford, Ore.; died in Ireland February 2, aged 45, of accidental asphyxiation.

Harry Dudley Miller @ Shelbyville, Ind.; University of Illinois College of Medicine, Chicago, 1934; commissioned as a first lieutenant on May 5, 1942 in the medical corps, Army of the United States; assigned to the 40th Station Hospital, Camp Barkeley, Texas; later promoted to captain; died in the North African theater February 2, aged 35, of injuries received when a boiler exploded.

James Douglas Noonan, Seattle; McGill University Faculty of Medicine, Montreal, Que., 1943; served as an intern at the Providence Hospital; commissioned a first lieutenant in the medical corps, Army of the United States, Oct. 23, 1943; died in Camp Barkeley, Texas, February 9, aged 25, of meningitis.

Clifford August Schmiesing, Salamanca, N. Y.; St. Louis University School of Medicine, 1929; member of the Medical Society of the State of New York; for many years school physician; commissioned a first lieutenant in the medical reserve corps of the U. S. Army on July 21, 1938 and began extended active duty in April 1941; later promoted to captain; died in Algeria January 21, aged 38, of a skull fracture received in an accident.

Bureau of Investigation

DAINGEROUS TO HEALTH

Because of Inadequate Warnings on Labels

[EDITORIAL NOTE.—These abstracts differ from other abstracts of Notices of Judgment issued by the Food and Drug Administration of the Federal Security Agency which have appeared in these pages in that they deal with nostrums which were misbranded because their labels failed to carry adequate warnings against giving them to children or using them in the pathologic conditions in which they might be dangerous to health, or caution against unsafe dosages or methods of duration of administration or application, for the protection of the user. The abstracts that follow are given in the briefest possible form; (1) the name of the product; (2) the name of the manufacturer, shipper or consigner; (3) the date of shipment; (4) the composition; (5) the type of nostrum; (6) the reason for the charge of misbranding, and (7) the date of issuance of the Notice of Judgment.]

Greenawalt's Compound Dandelion Liver Disks.—William G. Greenawalt, Norwalk, N. Y. Shipped March 26, 1941. Composition: essentially laxative plant drugs, such as podophyllum and aloes, with small amounts of belladonna and nux vomica alkaloids. Misbranded because label failed to give adequate directions for use or sufficient warning against giving to children or using in those pathologic conditions wherein it might be dangerous to health, or caution against unsafe dosage or methods of duration of administration, particularly in that it failed to warn that a laxative should not be taken when nausea, vomiting, abdominal pain or other symptoms of appendicitis are present, or that frequent use of product might result in dependence on laxatives, or that use of a medicine containing strychnine, as this did, might be especially dangerous to children and elderly persons.—[D. D. N. J., F. D. C. 706; April 1943.]

Kalis Capsules.—Kalis Products, Ottumwa, Iowa. Shipped Nov. 6 and Dec. 5, 1941. Composition: essentially acetanilid and laxative plant drugs, including podophyllum and cascara sagrada. Misbranded because labeling failed to give adequate warnings against use in those pathologic conditions wherein it might be dangerous to health, since labels did not caution against administering this product when symptoms of appendicitis are present, or to warn against unsafe methods or duration of administration, whereas frequent or continued use of product might be dangerous in causing serious blood diseases, anemia, collapse or dependence on the drug.—[D. D. N. J., F. D. C. 707; April 1943.]

Laneton for Women.—National Medicine Company, Nashville, Tenn. Shipped Jan. 10, 1942. Composition not stated. Misbranded because label did not give adequate directions for use as a laxative, which product was alleged to be, and further failed to bear adequate warnings against use in those pathologic conditions wherein it might be dangerous to health, or caution against unsafe duration of administration. Further misbranded because label was misleading in that it represented and suggested that the product was especially adaptable for use by women, whereas its effect would be the same on both men and women.—[D. D. N. J., F. D. C. 708; April 1943.]

Nurito.—Nurito Company, Chicago. Shipped Sept. 27, 1941, and Jan. 23, 1942. Composition: Each powder contained $\frac{1}{8}$ Gm. of phenolphthalein. Misbranded because label did not give adequate directions for use or sufficient warnings against administering in those pathologic conditions wherein it might be dangerous to health, or sufficient caution against unsafe duration of administration, since it did not adequately warn the user that the product should not be taken when certain stated symptoms of appendicitis are present, or that frequent or continued use might result in dependence on laxatives.—[D. D. N. J., F. D. C. 710; April 1943.]

Pon-Tam-Pon and Glycerant.—Pond Manufacturing Company, Rutland, Vt. Shipped Jan. 2, 1942. Composition: tampons and a tube labeled "Glycerant." Examination of "Medication A" tampon showed that it was essentially a gelatin shell containing a jelly composed of glycerinated gelatin, boric acid, ichthammol, iodine and a bundle of wool fibers. "Medication C" tampon was found to have the same composition except that it also contained silver nitrate, but no ichthammol. The Glycerant was found to be essentially boric acid in a jelly base. Articles misbranded because labels failed to give adequate warnings against use in those pathologic conditions wherein they might be dangerous to health, since labeling did not warn that they should not be used in case of gonorrhea. Further misbranded because of false and misleading label statements: "A tampon should be worn continuously and changed every 24 hours to obtain best results. . . but if profuse discharge is present, tampon should be changed every 12 hours until discharge is relieved. . .", which statements represented that the articles constituted effective treatments for discharge from the vagina and prolapse and backward displacement of the uterus.—[D. D. N. J., F. D. C. 711; April 1943.]

Shapley's Medicine for Acid or Sour Stomach.—Shapley Drug Company, Decatur, Ill. Shipped March 17, 1942. Composition: essentially extracts of plant drugs including rhubarb, with alcohol, sugar, potassium carbonate and water. Misbranded because labeling failed to give adequate directions for use, in that it provided for continuous administration of a laxative, which type of product should be taken for only occasional need. Further misbranded because label failed to warn adequately against use in those pathologic conditions wherein it might be dangerous to health, since labels failed to warn that the product should not be taken when abdominal pains, nausea, vomiting or other symptoms of appendicitis were present, or to caution against unsafe methods or duration of administration.—[D. D. N. J., F. D. C. 712; April 1943.]

Special Formula Tablets S. C. Purple.—Purity Drug Company, Passaic, N. J. Shipped Oct. 20, 1941. Composition: yohimbé bark, a strychnine compound, a magnesium compound, zinc phosphide, and extracts of plant drugs, such as damiana. Misbranded because labeling instruction, "Dose: To be taken as directed by physician," did not constitute adequate directions for use. Further misbranded because label failed to give adequate warning against administration to children, which use might be dangerous to health, or caution against unsafe dosage or duration of administration, since no caution was urged against frequent or long continued use, which might result in strychnine poisoning.—[D. D. N. J., F. D. C. 713; April 1943.]

Spicer's Compound.—Charles R. Spicer Company, Memphis, Tenn. Shipped Oct. 22, 1941, and Jan. 21, 1942. Composition: essentially a solution of epsom salt (about 25 per cent), with relatively small proportions of extracts of plant drugs, including laxatives, and a small amount of an iron salt, sweetened with saccharin and preserved with sodium benzoate. Misbranded because labeling failed to give adequate warnings against use in those pathologic conditions wherein it might be dangerous to health, since the label statement, "Caution—In case of severe abdominal pain, do not take a laxative," did not adequately warn purchasers against using this product when additional symptoms of appendicitis were present, or caution that frequent use of the product might cause a laxative habit; further misbranded because represented as a relief for various conditions which are due to causes other than occasional constipation; also misbranded because of label misstatements as to composition or as to proper terms of drugs present.—[D. D. N. J., F. D. C. 714; April 1943.]

Welltone.—Standard Chemical, Inc., Brooklyn, N. Y. Shipped Jan. 10, 1942. Composition: a solution of epsom salt (28 per cent), with inconsequential amounts of other salts, flavored with cassia and clove oils and sweetened with saccharin. Misbranded because label directions for use were inadequate and might result in dependence on laxatives. Further misbranded because the "lone" part of name represented that product would increase appetite, and statements in accompanying circular represented that mixture would increase appetite, prevent or cure headaches or run-down feeling, establish regularity in elimination, correct sluggish digestion or sour stomach, prevent weakening feeling due to constipation, eliminate any danger to general health, assist in digestive processes, and produce some other beneficial effects. Also misbranded because of label claim that the product complied with the federal Food, Drug and Cosmetic Act.—[D. D. N. J., F. D. C. 716; April 1943.]

MISBRANDED PRODUCTS

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the Federal Security Agency

[EDITORIAL NOTE.—These Notices of Judgment are issued under the Food, Drug and Cosmetic Act and in cases in which they refer to drugs and devices they are designated D. D. N. J. and foods, F. N. J. The abstracts that follow are given in the briefest possible form: (1) the name of the product; (2) the name of the manufacturer, shipper or consigner; (3) the date of shipment; (4) the composition; (5) the type of nostrum; (6) the reason for the charge of misbranding, and (7) the date of issuance of the Notice of Judgment—which is considerably later than the date of the seizure of the product and somewhat later than the conclusion of the case by the Food and Drug Administration.]

Gold Medal Compound Pills and Savatan.—S. Pfeiffer Manufacturing Company, St. Louis. Shipped Feb. 16, 1942. Composition: the pills consisted essentially of iron sulfate and small amounts of volatile oils, including spearmint. Savatan consisted of capsules each containing about 5 minims of apiol. Both products misbranded because of misleading label representations that they would relieve minor discomforts in menstruation.—[D. D. N. J., F. D. C. 736; April 1943.]

Green's Reliable Restorer.—A. J. Green, Clarksburg, W. Va. Shipped Feb. 16, 1942. Composition: essentially lead acetate and sulfate, zinc acetate, sulfur, alcohol, glycerin, oil of bay and water. Misbranded because of false and misleading representations on label that product would restore gray or faded hair to its natural color, free the scalp from dandruff and all contagious eruptions, stop hair from falling and promote and restore its growth.—[D. D. N. J., F. D. C. 737; April 1943.]

Herb Doctor Compound.—Strong, Cobb and Company, Cleveland. Shipped Sept. 25, 1941. Composition not stated. Misbranded because labeling failed to bear adequate directions for taking, since those given provided for its use under conditions which might have rendered it injurious to the user by creating a dependence on laxatives to move the bowels.—[D. D. N. J., F. D. C. 666; February 1943.]

Kotanko.—Block Drug Company, Jersey City, N. J. Shipped Dec. 22, 1941, and May 11 and June 2, 1942. Composition: essentially sulfur, pilocarpine, resorcinol and a camphoraceous oil, in an ointment base. Misbranded because label falsely represented that the product would discourage excessive loss of, and strengthen existing growth of, hair and help promote new growth, and that it was an efficacious treatment for dandruff, thin, brittle or falling hair and baldness. Further misbranded because made from two or more ingredients, whereas label did not give the common or usual name of each.—[D. D. N. J., F. D. C. 710; April 1943.]

Na-Stim.—Na-Stim Laboratories, Inc., Modesto, Calif. Shipped Nov. 24, 1941. Composition: essentially water, a gum, and fatty material. Misbranded because label claimed also the presence of menthol, Venice turpentine, oil of pine and iodine, whereas the government chemists' analysis did not detect the presence of the first three of these, and found merely a trace of combined iodine. Further misbranded because label falsely represented that product constituted relief from, and adequate treatment for, hay fever, sinusitis, head colds and other nasal disorders.—[D. D. N. J., F. D. C. 739; April 1943.]

O'Dara.—O'Dara Products Company, St. Louis. Shipped April 28, 1941. Composition (by percentages): alcohol, 46; glycerin, 17; methyl salicylate, 7; potassium iodide, 5; zinc chloride, 3, and phenol, 1, with unreported amounts of water, saccharin and myrrh. Misbranded because label falsely represented that it was an adequate treatment for pyorrhea, trench mouth, canker sores, stomatitis or spongy gums, that it would coagulate, detach and clear away objectionable matter, leave the tissues clean and stimulate healing processes; that it would kill disease producing organisms in the tissues, act as an adequate treatment for sore throat, form a protective film over wounds by coagulating the blood, and accomplish some other things.—[D. D. N. J., F. D. C. 738; April 1943.]

Omega Oil.—Block Drug Company, Jersey City, N. J. Shipped Dec. 22, 1941, and May 11 and June 2, 1942. Composition: essentially chloroform, methyl salicylate, mineral oil and a small amount of alkaloidal material such as hyoscyamus. Misbranded because label falsely represented that the product was different from ordinary liniments and was "far more than just liniment"; that it was a powerful and reliable answer to dozens of everyday ills; that at point of application it would soothe and ease the local nerves, stimulate the circulation, break up congestion, relieve rheumatic pains due to exposure, dampness and cold, alleviate athlete's foot and toe itch, and do some other things.—[D. D. N. J., F. D. C. 740; April 1943.]

Optic Drop.—Romero Drug Company, El Paso, Texas. Shipped Oct. 4, 1940. Composition: a watery solution of zinc sulfate, chlorobutanol, a berberine salt and boric acid or other borate. Misbranded because label falsely represented it to be beneficial for irritated eyes and failed to give the common or usual name of each active ingredient or a declaration of the quantity of the contents.—[D. D. N. J., F. D. C. 741; April 1943.]

Papaya Syrup.—Tropical Fruit Products, St. Louis. Shipped Feb. 25, 1941. Composition: an opaque, yellow, syrupy liquid containing essentially sugars, fruit acids, and orange and lemon oils, with papaya flavor. No active papain or other proteolytic enzymes found. Misbranded because label falsely represented that product would supply energy food which could be easily absorbed; that it would promote health and build energy, redress absorption of poisonous toxins in stomach distress, be an alkaliizer and body builder, prevent kidney, liver and stomach diseases and keep the skin clear; that it was an appropriate treatment for anemia, gastritis, indigestion, constipation, arthritis, rheumatism, ulcers, colitis, sinusitis, influenza, colds, dysentery and obesity, and would increase the stature of children.—[D. D. N. J., F. D. C. 636; February 1943.] Also misbranded under the provisions of the law applicable to foods, as reported in F. N. J. 3617.

Utona.—National Utona Company, Detroit. Shipped Oct. 18 and Dec. 2, 1941, and Jan. 12, 1942. Composition: essentially an extract of a saponin-bearing plant such as yucca, preserved with salicylic acid and sodium benzoate, colored with caramel and flavored. Misbranded because of false and misleading label representations that it would be efficacious as a relief for high blood pressure; would control the pressure and relieve the distressing symptoms; would lower high blood pressure of patients even in advanced years and render the body less toxic; would lessen the urge for frequent urination at night, impart a profound sense of well-being, and usually bring about improvement in symptoms such as pains in the back and neck, dizziness, headaches and tingling sensation; would help one sleep better and feel better and bring about a better relationship between the systolic and diastolic pressure.—[D. D. N. J., F. D. C. 742; April 1943.]

Vla-Min.—Universal Products Company, Cleveland. Shipped March 7 and 10, 1942. Composition: a liquid containing ferric sulfate (about 1,196 grains per gallon) and smaller amounts of the sulfates of aluminum, calcium and magnesium, with sodium phosphate. Misbranded because label carried false declaration of composition, and further represented in a lengthy list of ailments that product was virtually a cure-all. Among the disorders mentioned were such serious conditions as Bright's disease, diabetes, gallstones, cataract, anemia, arthritis, asthma, goiter and tuberculosis.—[D. D. N. J., F. D. C. 743; April 1943.]

Correspondence

MARIHUANA INTOXICATION

To the Editor:—As a result of the suppression, due to the war, of postal relations between the United States and Tunisia, I have only just learned of the work of Drs. Samuel Allentuck and K. M. Bowman entitled "The Psychiatric Aspects of Marihuana Intoxication" (*Am. J. Psychiat.* 99:248 [Sept.] 1942). I take the liberty of bringing to your attention the observations suggested to me by this communication:

(a) The authors say that their experiments were made by administering the drug orally: now in the countries where toxicomania through hemp is rife it is chiefly by smoking it that addicts consume the drug. The authors recognize, moreover, that a drug takes effect more rapidly (I may add, with greater intensity) when it is ingested.

(b) The symptoms of cannabis intoxication reported by the authors are well known and have been described many times in almost the same terms by those authors who have discussed the question (see the work of R. P. Walton "Marihuana" and the document of the League of Nations: O. C. Cannabis 3). A happy addition, Allentuck and Bowman have been able to give a few results of ophthalmoscopic examinations, data concerning blood pressure and the results of the application of various tests.

(c) Allentuck and Bowman declare that their clinical and laboratory studies, made on subjects accustomed and unaccustomed to marihuana, reveal no significant somatic or mental change. It is regrettable that it was not possible for them to examine a few of those inveterate hemp smokers that one meets in India, the Near East and North Africa, cachectic, stupefied, besotted, incapable of any sustained work: their opinion would certainly not be the one which they maintain.

(d) The symptoms which Allentuck and Bowman describe correspond very exactly to what one might call acute temporary intoxication by cannabis and not to chronic intoxication.

I have pointed out, in my reports to the League of Nations, that many hemp smokers in North Africa confine themselves reasonably to relatively slight doses and frequency of absorption: they smoke, daily, 6 or 8 pipes of hemp, as we smoke 10 to 20 tobacco cigarettes. If they confine themselves to this, there is no danger. As for those who, less wise, have not the will to resist the attraction of the narcotic, they are headed for chronic intoxication, which leads them little by little to the most complete physical and moral decay.

To tell the truth, these unfortunates only rarely reach dementia. They are not encountered in the insane asylums: it is in the class of thieves (la "pègre"), made up of professional beggars, prowlers and robbers, that they fall. It would be superfluous to amplify this subject: it is set forth at length in Document O. C. Cannabis 3 of the League of Nations (pp. 51 to 66). Nevertheless it must be noted that the most serious accidents are observed in individuals consuming hashish (charas, chira); that is to say, the crude resin, and not in smokers of the plant itself, in its natural state. In fact, whereas the plant is shown to contain on an average from 5 to 8 Gm. of crude resin per hundred grams, hashish contains from 35 to 47 per cent of it. Until recently hashish (charas) was unknown in America: now, the last report of the United States government (1942) on the traffic in opium and other dangerous drugs mentions (p. 30) two seizures of charas. The notice is serious and big with disturbing consequences. In fact, if it becomes possible for them to consume charas, marihuana addicts will quickly suffer from accidents much more severe than those confirmed by Allentuck and Bowman.

The 77 subjects who underwent the experiments of Drs. Allentuck and Bowman (and this takes away a great deal of their value from the conclusions of these authors) were hos-

pital patients, even, it appears, prisoners. They were therefore obliged to be content with the quantities of drug administered to them. At liberty, some of them would have given free rein to their inclination and would not have stopped at the weak dose producing "the pleasure principle." It is because they can procure the drug at will, because they can consume as much of it as they wish and as often as they desire it, in the Oriental countries (where traffic in the drug is not prohibited or regulated), that there is such a large number of serious chronic cases of intoxication, the addicts being incapable of working, wretched ragamuffins who are a danger and a burden to society. These consequences alone would justify the prohibition of and a declaration of war on marihuana.

(c) There is not, say Allentuck and Bowman, any special characteristic psychosis due to marihuana. That may still be true, at present, in the United States, for a population in which the old hemp addict does not yet exist. That is why the remark of Dr. Lawrence Kolb (in the course of the discussion of the communication of Allentuck and Bowman) must be kept in mind: "the experiments ought to be made in a country like Mexico, where the use of marihuana is widespread."

The serious chronic hemp addict will perhaps never be produced in the United States, thanks, first, to the wise measures of prohibition and supervision taken and also because (if account is taken of what is found to be true in the Orient and in North Africa) it cannot be denied that serious chronic hemp intoxication makes hardly any victims except among the native population. The European, if, out of curiosity, he occasionally consumes hemp, does not make a practice of this intoxication: the form of drunkenness produced by it does not suit his temperament, his mentality. On the other hand, the poison appears perfectly adapted to the mentality of the Orientals, who have used it for almost eight centuries; but it is incontestable that it establishes in them a characteristic psychosis, which never escapes the doctor accustomed to seeing this sort of patients.

(f) Allentuck and Bowman say that cannabis intoxication is extremely variable in its manifestations. It is just there that one of its greatest dangers exists, for one does not know, and cannot foresee, how it will show itself. Certain addicts are driven, under the influence of hemp, to irresistible and dangerous impulses, whereas in others one finds only mental instability and reactions without danger for others. The attack varies, in short, with the culture, the sensitiveness and the intelligence of the subject: an apathetic person will have a calm and mild delirium; an imaginative one will have brilliant and varied hallucinations; a brute will have savage reactions, accesses of mad rage: Dr. Blondel once wrote "Every hashish addict has the dream which he deserves." That is, moreover, why psychoanalysts have proposed the use of cannabis to reveal the subconscious. This is quite all right when it is a question of supervised clinical experiments, but in everyday life is it not to be feared that in many cases tendencies and propensities will emerge from the subconscious of a goodly number of individuals which it would have been much better to leave buried forever?

(g) It has likewise long been noted that hemp was not an aphrodisiac; like certain other sensorial drugs, it produces, in certain consumers, sexual excitations psychic in character but without any physical effect. It is, moreover, notorious that hashish addicts no longer experience any sexual desire: women no longer interest them; they frequently fall, for a time, into sexual perversion, then, sobered, they are content to live "with their pipe and their pot."

(h) Allentuck and Bowman maintain that the relations between marihuana and crime are unfounded. This opinion, based on 77 tests applied to persons not living at liberty, appears bold. This has not escaped Dr. Lawrence Kolb, who expresses his reservations: "One may say of such a drug that, if it were abused as alcohol is abused, it might be an important cause of crimes and other misdemeanors."

Now, the statistics of the Narcotics Bureau in Washington are already eloquent on this subject; the annual reports of the Egyptian government to the League of Nations are no less so, as well as the various documents published in the course of the inquiries of the League of Nations.

"Hachichins" [hashish addicts] do not all become assassins (a reference to the medieval legend of the Old Man of the Mountain and his band of Assassins; the word "assassin" is derived from "hashish"). But their laziness, their amorality, indubitably lead them to commit criminal acts if only in order to procure the money necessary for the regular purchase of the drug. This road leads far and sometimes ends in crime.

(j) It is correct—and well known—that accidents from privation have not, with cannabis, the seriousness which they attain for users of manufactured drugs, even opium. Nevertheless, quite serious disorders are observed in those addicted to the drug over a long period when their poison is removed. Attacks of physical prostration and intellectual apathy, especially, are noted: the patient remains in a corner, prostrated, refusing to move, neglecting to eat.

(k) The use of marihuana to combat disorders due to the abuse of narcotics and to chronic alcoholism appears paradoxical. With individuals able to avail themselves freely, outside of all medical control, of a substitute drug analogous to the one of which one desires to have him [sic] break the habit, one will succeed only in replacing one intoxication by another.

I am willing to admit that certain persons afflicted with toxicomania who took a cure for intoxication by means of marihuana under the supervision of Drs. Allentuck and Bowman found accidents from privation improved by this substitution, that they were in better form as regards morale and bodily energy and were desirous of resuming their occupations more quickly. But I still maintain that at least 95 per cent of the persons suffering from toxicomania who have been forced to undergo a cure for intoxication have only one desire, on leaving the clinic; to wit, to procure their favorite drug quickly and to become addicted to it once more. There is therefore no reason to accustom them, in the course of treatment, to a substitute drug: that would be furnishing them two means of satisfying their vice, when they are no longer under the supervision of the hospital personnel.

I therefore share to the full the opinion of Dr. Lawrence Kolb: "By proposing the use of marihuana in the treatment of toxicomanias and chronic alcoholism, Drs. Allentuck and Bowman are entering dangerous territory and the result can be only the substitution of one toxicomania for another."

In conclusion, however interesting the results of the researches of Drs. Allentuck and Bowman may be, from certain points of view, it is my opinion that they have been made known to the public prematurely. In exclusively medical circles, such communications present no danger; on the contrary, they provoke discussions and new investigations which may throw light on the disputed points. But it is to be feared that the general public will retain especially what is not irrefutably proved by the work of Drs. Allentuck and Bowman; to wit, that marihuana is not as dangerous as it is said to be, that it induces pleasant sensations without the risk of baleful consequences and that it may constitute a valuable method of treatment in certain afflictions.

The use of marihuana must be prohibited on the same grounds as that of opium and the manufactured narcotics, and the social interest of the civilized countries demands that the strictest prohibition measures be taken and enforced.

J. BOUQUET, M.D.,
Hospital Sadiki, Tunis.

Expert on the Narcotics Commission
of the League of Nations.

Medical Examinations and Licensure**COMING EXAMINATIONS AND MEETINGS****NATIONAL BOARD OF MEDICAL EXAMINERS
EXAMINING BOARDS IN SPECIALTIES**

Examinations of the National Board of Medical Examiners and Examining Boards in Specialties were published in *THE JOURNAL*, March 25, page 947.

BOARDS OF MEDICAL EXAMINERS

ALABAMA: Montgomery, Oct. 24-26. Sec., Dr. B. F. Austin, 519 Dexter Ave., Montgomery.

ALASKA: Juneau, September 5. Sec., Dr. W. M. Whitehead, Box 561, Juneau.

ARIZONA: Phoenix, April 4-5. Sec., Dr. J. H. Patterson, 826 Security Bldg., Phoenix.

ARKANSAS: * Eclectic. Little Rock, June 8. Sec., Dr. C. H. Young, 1415 Main St., Little Rock.

CALIFORNIA: San Francisco, June 27-29. Sec., Dr. Frederick N. Scatena, 1020 N St., Sacramento.

COLORADO: * Denver, April 4-7. Sec., Dr. J. B. Davis, 831 Republic Bldg., Denver.

DELAWARE: Dover, Oct. 10-12. Sec., Medical Council of Delaware, Dr. J. S. McDaniel, 229 S. State St., Dover.

FLORIDA: * Jacksonville, June 26-27. Sec., Dr. W. M. Rowlett, Box 786, Tampa.

ILLINOIS: Chicago, April 4-6. Supt. of Registration, Department of Registration and Education, Mr. Philip Harman, Springfield.

INDIANA: Indianapolis, May 2-4. Sec., Board of Medical Registration and Examination, Dr. W. C. Moore, 301 State House, Indianapolis.

KENTUCKY: Louisville, Sept. 11-12. Sec., State Board of Health, Dr. Philip E. Blackerby, 620 S. Third St., Louisville.

MARYLAND: Medical. Baltimore, June 13-16. Sec., Dr. John T. O'Mara, 1215 Cathedral St., Baltimore. Homoeopathic. Baltimore, June 20-21. Sec., Dr. J. A. Evans, 612 W. 40th St., Baltimore.

MINNESOTA: * Minneapolis, April 18-20. Sec., Dr. J. F. DuBois, 230 Lowry Medical Arts Bldg., St. Paul.

MISSOURI: St. Louis, August. Sec., State Board of Health, Dr. James Stewart, State Capitol Bldg., Jefferson City.

MONTANA: Helena, April 3-5. Sec., Dr. O. G. Klein, First National Bank Bldg., Helena.

NEVADA: Carson City, May 1. Sec., Dr. G. H. Ross, 215 N. Carson St., Carson City.

NEW MEXICO: * Santa Fe, April 10-11. Sec., Dr. LeGrand Ward, 141 Palace Ave., Santa Fe.

NEW YORK: Albany, Buffalo, New York City and Syracuse, June 26-29. Sec., Dr. R. R. Hannon, Education Bldg., Albany.

NORTH CAROLINA: Raleigh, September. Sec., Dr. W. D. James, Hamlet.

NORTH DAKOTA: Grand Forks, July 5-8. Sec., Dr. G. M. Williamson, 4½ S. Third St., Grand Forks.

OHIO: Endorsement. Columbus, April 4. Sec., Dr. H. M. Platter, 21 W. Broad St., Columbus.

OREGON: * Endorsement. Portland, April 22. Exec. Sec., Miss L. M. Conlee, 608 Failing Bldg., Portland.

RHODE ISLAND: * Providence, April 6-7. Chief, Division of Examiners, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

SOUTH CAROLINA: Columbia, June 26-28. Sec., Dr. N. B. Heyward, 1329 Blandens St., Columbia.

WEST VIRGINIA: Charleston, May 1-3. Commissioner, Public Health Council, Dr. John E. Offner, State Capitol, Charleston.

WISCONSIN: * Milwaukee, June 27-29. Sec., Dr. C. A. Dawson, Tremont Bldg., River Falls.

WYOMING: Cheyenne, June 5-6. Sec., Dr. M. C. Keith, Capitol Bldg., Cheyenne.

* Basic Science Certificate required.

and Legislation****MEDICOLEGAL ABSTRACTS**

Malpractice: Alleged Excessive X-Ray Dosage in Treatment of Barber's Itch.—Simon developed so-called "barber's itch" on his face in February 1941. His face became swollen, many pustules were exuding pus, the skin became cracked and bleeding, and there were some scabs. About May 17 he went to a clinic conducted by the Chicago Medical School, where he was examined and referred for treatment to the defendant, Kaplan, an associate professor of radiology at that school, who, so he testified, for over twenty years had limited his practice to roentgenology. May 29 the patient was subjected to x-ray therapy, the exact nature and extent of which is in dispute. The physician stated that each side of the patient's face was exposed to an x-ray machine for three and one-half minutes and that each side of the face received 217 r units. On the other hand, the patient stated that each side of his face was exposed ten minutes and a card, a part of the physician's office record relating to the patient, read "three and a half minutes to each side of the face, 500 r." The physician stated, however, on cross examination, in the words of the court, "with some uncertainty and hesitation that the 500 r which appeared on the card was the number of units he intended to give plaintiff and that he had not given him more than 217 r's during the treatment, on each side of the face." In any event, the patient returned to the physician in about two weeks, at which time his face was red and the physician gave him some salve, instructing him to return in a week to ten days, when he would give him another x-ray treatment. The patient, however, never returned but instead, on June 19, consulted Dr. Caro, a dermatologist. Just what the trouble was the reported case does not make satisfactorily clear. Apparently, however, the hair on the patient's face fell out permanently, the skin atrophied "with discoloration," there was "thinning of the skin, with erosions," and there was an enlargement of the veins. Alleging that that condition was due to negligence on the part of the physician in applying the x-ray treatment, the patient instituted an action for malpractice.

At the trial Dr. Caro, the dermatologist consulted by the patient, testified that he diagnosed the patient's condition when he was consulted that day as "an acute dermatitis, produced, probably, by radiation. That is x-ray." He stated that he treated the patient a number of times later, that the patient's condition improved in September or October 1941, that at the time of the trial the patient "shows the effects that we usually see in chronic x-ray burn" and that in his opinion, if proper dosages of x-ray had been applied, the present condition of the patient would not have developed. Dr. Uhlmann, who specialized in "radiotherapy, x-ray, diagnostic and therapeutic," was also called as a witness at the trial by the patient and he testified "that he saw plaintiff a few days before the trial and observed in his face several signs of disease which he proceeded to mention; that the condition he found on the upper part of the face 'could not be due to barber's itch or the after effects of barber's itch.'" In answer to a hypothetical question he testified that the logical conclusion is that the patient received more x-ray to the upper part than he received in the lower part of his cheeks and that in his opinion the treatment mentioned in the hypothetical question propounded to him "would not be usual and customary for a specialist to apply enough x-ray to bring about a condition of atrophy of the skin, thinning of the skin, with erosions." The defendant physician himself testified that the treatment he gave the patient was "the same kind of treatment ordinarily and customarily given by me to patients suffering from the barber's itch. In fact, he received a less number of r units than I have given to quite a number of others." As noted before, Kaplan testified that he gave the patient 217 r units on each side of the face, making a total of 434 r units, but his record card of the case bore a notation of 500 r, which he stated on cross examination was what he intended ultimately to give to the patient. The defendant called as a witness Dr. James T. Case, "practicing specialty radiology," who, in answering a hypo-

thetical question, testified that a total dosage of 500 r units to be given in two different treatments was quite within the ordinary and usual proper practice and that if 500 r units were given to each cheek in one treatment, "That would be somewhere near the upper limit of the proper dosage, it wouldn't be far from it." The defendant also called as a witness Dr. I. S. Trostler, also a radiologist, who in answer to a hypothetical question said that if 217 units were given in the treatment of barber's itch he would consider that according to the usual practice of physicians of skill in using x-ray in Chicago and that if the patient was given 500 r units on each cheek in a treatment he would think this was the proper practice. There was a judgment for \$4,500 in favor of the patient and the physician appealed to the appellate court of Illinois, first district, first division.

Apparently, preliminary to an argument on the specific respects in which the defendant contended that the trial court had erred, the defendant argued that before a recovery can be had in a malpractice case it must be shown by affirmative evidence that the physician was unskilful and negligent, that his want of skill caused plaintiff's injury and, further, that the liability of a physician for injuries caused by the misuse of an x-ray machine rests on the same principle of law as on any other branch of medicine or surgery. Both of these propositions, said the appellate court, are correct statements of the law. Specifically, the defendant contended (1) that the trial court erred in permitting medical expert witnesses called by the patient to testify directly that the x-ray treatment caused the plaintiff's condition rather than that the treatment might or could have caused the condition and (2) that this action on the part of the trial court was contrary to the rule of law in force in Illinois. It might to some slight extent appear, answered the court, that the patient's expert witnesses testified directly that the x-ray treatment given caused the patient's condition, but on examination of their testimony we think it clear that they were but giving their opinion that the treatment might or could have caused the patient's condition and the jury was not misled.

It was next contended that the diagnosis of the patient's expert witnesses that the patient's condition was due to x-ray exposure is not supported by the facts. The court, however, was unable to say that the jury was not warranted in finding that the treatment given had been negligent. The patient called two physicians who gave testimony tending to show that the defendant had been negligent in treating the patient. On the other side, the physician and two other medical expert witnesses gave testimony to the contrary. In these circumstances we are not warranted in disturbing the verdict of the jury.

The physician next contended that the court erred in the giving of two instructions, Nos. 15 and 16. Instruction No. 15 told the jury that if under a preponderance of the evidence and instructions of the court the jury found the issues for the patient and that the patient had sustained damages by reason of physical pain and suffering undergone by him as a natural, direct and proximate result of the negligence of the defendant, as charged and alleged by the plaintiff, then there should be a finding for the patient. The physician contended that insofar as this instruction in effect told the jury that if they found from a preponderance of the evidence that the plaintiff suffered damages as a result of the defendant's negligence, it in effect assumed that the defendant was negligent. We think this objection, answered the court, is hypercritical and while it would have been better to have told the jury that if they found the patient suffered damages as a proximate result of the defendant's negligence, if any, yet it did not direct a verdict, and we think the jury were not misled because they were told in another instruction that if they believed from the evidence that the defendant used ordinary care and skill in his treatment and exercised his best judgment then it was their duty to find the defendant not guilty. Moreover, the instruction told the jury that they must find the patient was damaged as a result of the physician's negligence "as charged and alleged" by the plaintiff in his complaint. The complaint made to instruction No. 16 was that it instructed the jury that in fixing the plaintiff's damages it might take into consideration the plaintiff's marred personal appearance. But, said the court, in *Fitzgerald v. Davis*, 237 Ill. App. 488, we held that the plaintiff's marred personal appearance was a proper element for the jury to consider in fixing the damages. We there said:

The law only prohibited the recovery of damages in such a case for mental suffering which results from embarrassment or chagrin and which suffering has no relation to physical pain . . . She might recover for disfigurement which resulted from the accident

Of course, continued the court, every one knows that the disfigurement of one's face which is the result of a defendant's negligence often may cause damages, for example, plaintiff may be unable to secure employment on account of such disfigurement.

The judgment of the trial court in favor of the plaintiff was accordingly affirmed.—*Simon v. Kaplan*, 52 N. E. (2d) 832 (Ill., 1944).

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1934 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American J. Digestive Diseases, Fort Wayne, Ind.

11:1-30 (Jan.) 1944

Review of Hypoglycemia, Its Physiology and Pathology, Symptomatology and Treatment. H. E. Himwich—p. 1.

*Salmonellosis Caused by the Ingestion of Ducks' Eggs I. Snapper—p. 8.

Treatment of Chronic Ulcerative Colitis C. J. Drueck—p. 10.

Influence of Diet on Sulfonamide Action Esther M. Greisheimer, Robert Hafkesbrung and Grace E. Wertenberger—p. 13.

Salmonellosis Caused by Ingestion of Ducks' Eggs.—

Snapper directs attention to the fact that outbreaks of paratyphoid fever C and allied types of salmonellosis may occur if raw or insufficiently cooked ducks' eggs are used in the preparation of ice cream, sauces, puddings, pies or mincemeat, foods that may be put away for hours before they are consumed. *Salmonella* organisms may multiply rapidly and infection of human beings may result if the foods are eaten. In the United States ducks' eggs are rarely used for human consumption, and salmonellosis of this source is therefore rare. In the Orient, particularly in China, ducks' eggs are widely used and this may be a factor in the frequent occurrence of salmonellosis in that country. In the Netherlands East Indies investigations have been carried out on ducks' eggs, and *Salmonella typhi* murium has been detected in 8 of a total of 300 ducks' eggs.

American Journal of Physiology, Baltimore

Effect of Repeated Determinations on Basal Metabolism of Children. R. C. Lewis, Anna Marie Duval and A. Iliff—p. 461.

Effect of Damage to Tracheal Mucosa on Drainage of Respiratory Tract Fluid E. M. Boyd, W. F. Perry and Mary E. T. Stevens—p. 467.

Carbohydrate Regulation Under Severe Anoxic Conditions. L. Van Middlesworth, R. F. Kline and S. W. Britton—p. 474.

Effect of Sulfonamides on Blood Oxygen and Carbon Dioxide Capacity, Arterial Saturation and Blood Pigments J. F. Hall Jr.—p. 483.

*Nervous Factor in Shock Induced by Muscle Trauma in Normal Dogs. W. J. Eversole, W. Kleinberg, R. R. Overman, J. W. Remington and W. W. Swingle—p. 490.

Changes in Renin-Angiotensin System in Hemorrhagic Shock D. A. Collins and Angie S. Hamilton, with technical assistance of Margaret Casey Collins and A. Sokolchuk—p. 499.

Further Study of Boron in Nutrition of Rat. J. D. Teresi, E. Hove, C. A. Elvehjem and E. B. Hart—p. 513.

Comparison of Renal Reabsorptive Processes for Several Amino Acids. R. F. Pitts—p. 535.

Relation Between Uric Acid Excretion and Hippuric Acid Synthesis in Man S. T. Michael, J. M. Looney and Embrie J. Borkovic—p. 548.

Testing of Color Vision in Relation to Vitamin A Administration. W. F. Hamilton, A. P. Briggs and R. E. Butler—p. 578.

Relation of Heart Rate to Slow Waves in Electroencephalogram During Overventilation. C. W. Darrow and J. H. Pathman—p. 583.

Effect of Crystalloidal and Protein Containing Solutions on Body Fluids and Circulating Plasma Proteins. C. T. Ashworth, Z. W. Hutcheson, W. T. Payne and A. W. Jester—p. 589.

Radioactive Phosphate as an Indicator of Relationship Between Phosphate Changes of Blood, Muscle and Liver, Following Administration of Insulin. N. O. Kaplan and D. M. Greenberg—p. 598.

Effect of Thiamine Deficiency and of Reduced Food Intake on Resistance to Low Oxygen Tension in Cat. D. C. Smith, R. H. Oster and J. E. P. Loman—p. 603.

Nervous Factor in Shock.—Eversole and his collaborators found that traumatization of the muscles of both hind legs by 800 to 1,600 blows with a light rayhite mallet, in which the skin was not ruptured or bones fractured, produced fatal shock in 14 of 15 dogs. The survival periods ranged from two to eight hours, with an average of four hours after the completion of the trauma. Spinal anesthesia maintained for three to four hours prevented all symptoms of shock and allowed uneventful recoveries in 10 of 12 animals. A local anesthesia of the legs by means of pressure (tight tourniquets) maintained for a two

hour period protected 7 of 12 dogs against shock and considerably prolonged the survival of 4 more. Thorough infiltration of the areas to be traumatized with a 4 per cent procaine solution, repeated frequently over a three to four hour period, prevented fatal shock in 7 of 10 dogs. The evidence indicates that a flow of nociceptive stimuli from the traumatized regions, unless prevented by spinal anesthesia or a local block, is an important contributing factor in the initiation of the shock state which follows the described type of muscle trauma.

*Rupture of Rectosigmoid by Compressed Air: Case Report. S. A. Swenson Jr., and H. N. Harkins—p. 141.

Sulfonamides in Fresh and Contaminated Wounds.—

Holman applied in the management of wounds a mixture of equal parts of sulfanilamide and sulfathiazole powder or crystals in generous amounts to every pocket and crevice of the wound at the earliest possible moment. The application of the drug should be repeated when débridement is performed. When operating in a dirty or potentially contaminated wound, as drying a débridement or in the closure of a colostomy, the drug mixture should be applied as the operation proceeds and as freshly incised areas are exposed in the operative field. In open resections of the intestinal canal, in lobectomy or pneumonectomy, the raw surfaces of incised tissues should be impregnated with the drugs before opening the viscus or the bronchus. In localized or general peritonitis the drug should be brought into contact with all contaminated surfaces. Mixed with blood and tissue fluids, the drug is thinly smeared or rubbed over all infected peritoneal surfaces, insuring maximum absorption and least interference with healing. Dumping large masses of the dry powder into a wound is inviting poor healing, as it may then act as a foreign body. "Frosting" a wound reaches only the superficial surfaces. After operation, when vomiting or gastric suction prevents their oral administration, the drugs may be administered subcutaneously, intravenously or rectally. Sulfanilamide may be administered by hypodermoclysis in 0.8 per cent watery solution. Five Gm. of sodium sulfathiazole dissolved in 100 cc of distilled water may be given intravenously twice daily. Sulfanilamide may be given intravenously every six hours as a 1 per cent solution. Four to 6 Gm. of sulfanilamide powder suspended in 100 cc. of tap water may be administered by rectum. Orally, 4 to 6 Gm. of the sulfonamides may be given as the initial dose, and 1 Gm. every four hours thereafter. Apparent cyanosis, a scarlatiniform rash or a high unexplained fever demand the discontinuance of the drug. A daily urinary output of at least 1,000 cc. is imperative, and 1,500 cc is preferable. Many cases, including compound injuries of the extremities, skull, thorax and abdomen, have been treated successfully according to these principles.

Treatment of Pain with Procaine Injections.—Gorrell injected procaine, nupercaine or eucupin to 295 patients to counteract pain. Sprained ankle, osteoarthritis or rheumatic conditions were the chief causes of pain. The relief of pain by local anesthetic injections does not free one from the responsibility of determining a possible serious cause for the pain. The so-called trigger point should be ascertained before the injection is made. If the patient does not wince when pressure

is made on a point, it is probably not the one sought. If finger tip pressure causes the patient to say "That is my pain," one may confidently predict relief. If several areas of tenderness are found, each should be indicated with a skin marking pencil or a drop of colored antiseptic solution. Only those causing wincing tenderness should be injected. Procaine injections will cure the great majority of muscle, fascia and ligament pains. Relief is only temporary, though often gratifying, if an organic cause is still at work. In the long term view such injections must be considered as only a part of the treatment of osteoarthritis and rheumatic conditions. The correction of posture, removal of foci of infection, reduction of weight, avoidance of chilling and overwork and the daily use of "limbering up" exercises must all be considered.

Rupture of Rectosigmoid by Compressed Air.—The subject of the report by Swenson and Harkins was a man aged 43 who was hospitalized from an industrial plant with the history that an hour before admission, while he was bending over, a fellow worker turned a compressed air hose at the patient's buttocks and released a sharp blast of air. The patient fell to the floor, immediately felt sharp abdominal pain and noted that he was "blown up like a balloon." Physical examination was negative except for considerable abdominal distention, rigidity and tenderness. The abdomen was highly tympanitic to percussion. A diagnosis of traumatic perforation of the rectosigmoid was made and immediate operation was decided on. Continuous gastric suction was begun and the operation was done under spinal anesthesia. When the peritoneum was opened, at least 2 liters (possibly 3 to 4 liters) of air gushed out under sufficient pressure to cause a whistling sound and resulting in appreciable collapse of the distention. The bowel was explored from one end of the rectum to and including the stomach, and four lacerations in the rectum and rectosigmoid were found. The remainder of the bowel showed considerable edema. The lacerations were repaired and the patient's recovery was comparatively uneventful. This case brings the total number of cases of rupture of rectum and of rectosigmoid caused by compressed air to 64. Immediate operation is indicated when the condition is diagnosed or suspected.

Rheumatic Diseases and Tuberculosis.—Loewenstein emphasizes that it is the presence of tubercle bacilli in loco morbi that proves the nature of the disease and not the reaction of the tissue. The tubercle is only a facultative phase in the life cycle of the tuberculous focus. The presence of the tubercle bacilli is a direct proof, the reaction of the tissue an indirect evidence. Roessle came to the conclusion that tuberculosis and rheumatism are two representatives of allergic disease and that Aschoff's nodules represent the anatomic substratum of allergy. It has been shown that rheumatism is a disease not of the joints alone but of the whole mesenchyme. Tubercle bacilli have been found in the blood and joint fluid of patients suffering from acute rheumatic fever, endocarditis and chorea. Tubercle bacilli have been found post mortem in the blood, heart, spleen and tonsils and in rheumatic polyarthritis, endocarditis and chorea. They may be demonstrated in the appar-

ently normal spinal fluid of patients with chorea and sometimes in the urine. Lymph nodes in the neighborhood of affected joints show many fresh tubercles and bacilli in microsections. The anatomic appearances, especially of the heart, rather approximate those of tuberculosis than those of streptococcal infection. Streptococci are rarely found in the blood; they cannot produce serous effusions. The sedimentation rate of rheumatic fever is closely similar to that in miliary tuberculosis. Tubercle bacilli can be found not only in the blood of patients with rheumatic eye diseases but also in the tissues of the eye in cases of iritis, iridocyclitis, choroiditis and sympathetic ophthalmia. Foci similar to the foci in miliary tuberculosis can be found by ophthalmoscopy in 61 per cent of the cases of acute rheumatic fever. Aschoff's nodules are frequently found in the heart of the tuberculous cadavers without rheumatism in the clinical history. Untreated patients with rheumatic fever have developed miliary tuberculosis. Antibodies against tubercle bacilli are present in over 80 per cent of rheumatic patients. The curve of tuberculin sensitivity shows a characteristic change from anergy in the first few days to hyperergy in the convalescence. The treatment with tuberculin in homeopathic doses has been recommended. The same anatomic appearances as those found in rheumatic fever can be produced by pure strains of tubercle bacilli after reinjection in the peritonsillar region of rabbits. The occurrence and the recurrence of rheumatic fever are dependent on an endogenous or exogenous reinfection; superimposed infections may mobilize sleeping foci of tubercle bacilli.

Comparative Value of Various Parenteral Fluids.—Bradach reviews the physiologic factors that enter into the maintenance of a normal body fluid balance, giving particular attention to the role of water, the electrolytes and the blood proteins. Crystalloids are effective for replacing lost electrolytes and for combating metabolic disease. Because of ready diffusibility, crystalloids generally are not satisfactory as supportive agents in hemorrhage or shock. Acacia, because of its toxic effects, is not entirely satisfactory as a parenteral supportive fluid even though it possesses suitable colloidal properties. Bovine plasma, bovine albumin, isinglass, crystalline hemoglobin, human ascitic fluid, cadaver blood and placental blood, because of limited availability or uncertain properties, cannot be considered practical agents for general parenteral use. Pectin, because of its plasma-like osmotic properties, easy availability and nonantigenic qualities, has promise of being a suitable supportive agent for parenteral use. Human serum albumin and human plasma are agents of unquestionable value as parenteral supportive fluids. Ease of storage and transport and the stability of these agents make them highly valuable as blood substitutes. Whole blood remains the best agent for treatment of acute blood loss or shock.

Acrylic and Elastic Resin Prostheses for Facial Deformities—Swezey and her collaborators call attention to a new synthetic resin for surgical prostheses. The resin is an acrylic substance. It comes in the form of two powders (pink and colorless) and a liquid which binds them. Small quantities of other colors also are supplied. These powders can be mixed in varying amounts until the required shade and translucency is obtained. An elastic resin has been developed recently which, after processing, is rubber-like in many of its characteristics and is processed, like acrylic resin, with heat and pressure. The authors have made an ear, part of a nose and a whole nose of both elastic and the acrylic resin and have found the former to be a more suitable medium, although the latter has many desirable qualities. All 3 of the patients for whom the authors made prostheses had carcinoma. The partial nose is a temporary restoration until a surgical operation can be performed, but the other two are permanent prostheses. The resin is light, translucent and easily manipulated and is unaffected by ordinary heat, cold, moisture and light. It is tolerated by tissues, easily duplicated from the original mold and inexpensive. It can be trimmed and repaired with a hot spatula. It can be stained in a graduation of shades.

Sex Hormones in Angina Pectoris and Peripheral Vascular Disease.—Patients were chosen for this treatment who had the typical syndrome of pain on effort relieved by rest and glyceryl trinitrate and who had other signs suggesting that the angina was arteriosclerotic in origin. All of these patients had suffered from angina for a period of from several months to several years and they knew the relief they obtained from glyceryl trinitrate. Patients were asked to keep a day by day record of anginal attacks and the number of glyceryl trinitrate pills necessary in each day to control attacks. All were started on a series of twelve injections given at intervals of four to five days; some received more and some less. In men each injection consisted of 25 mg. of testosterone propionate and in women each injection was 5 mg. of estradiol dipropionate. Only 4 cases of peripheral vascular disease were treated. Seventeen of 20 patients with angina pectoris showed some improvement. Of these 6 showed fairly definite improvement which lasted from three months to one year; the rest showed slight to moderate improvement which did not last long after treatments stopped. Of the 4 patients with peripheral vascular disease treated 1 reported considerable and 2 slight improvement. The fourth reported no improvement. None of these patients showed definite change in pulsation in the dorsalis pedis arteries.

Influence of Draft on Psychoses in Women.—Wallenberg says that among the female admissions at the Manteno State Hospital there were a number whose histories indicated that the onset of mental symptoms was connected with the prospective or actual draft of a near relative. The records of 12 such patients were carefully studied. Objective exploration revealed that in no case was the drafting of a love object the only precipitating factor. Other severe traumas were present (the death of a brother, a drunken husband, disappointment in love), all clearly showing the conflict of ambivalence. In many cases the draft merely represented a rationalization, a displacement from the conflict centering around the actual or ideational loss of an ambivalently loved person. The inner need for rationalization unconsciously finds expression in the information advanced by relatives and friends who seek to explain the symptoms of the patient in terms of concrete causes. The information from relatives, although rendered in good faith, proved to be misleading with regard to the actual onset or origin of the psychosis.

Flicker Fusion Tests as Measure of Fatigue in Aviators.—Graybiel and his associates point out that in a study of the fatigue which results from mental stress or hazardous occupation rather than muscular effort the most pressing problem is establishing some objective measure of the fatigue. A study by the U. S. Public Health Service on fatigue in truck drivers indicated that flicker fusion tests, in addition to a battery of psychomotor tests, gave some evidence of the deterioration which occurred. The authors studied the flicker fusion test as a measure of fatigue in aviation pilots. The 32 subjects tested were naval aviators acting as instructors. Their

flight duties consisted in dual instruction and the supervision of formation flights. Flicker fusion levels were measured when the pilot reported to the squadron in the morning and again shortly after completion of the last flight of the day. At the time of the flicker measurement data were recorded regarding hours of sleep during the preceding night, time of last meal, hours flown and sense of being "tired" or "not tired." Control observations were made on days when bad weather prevented flying. Flicker fusion was tested by means of an electronic oscilloscope. One hundred and forty-three double determinations of flicker fusion were made. No significant correlation was discovered between the alteration in flicker fusion frequency and the state of fatigue. The flicker fusion test offered no promise as an objective measure of fatigue in aviation.

Airsickness in Bomber Crews.—Green made a survey of 1,006 flying personnel in a combat bomber crew training unit. An average of 1 in 6 of all personnel suffered attacks of airsickness regardless of previous air experiences. Symptoms vary widely in the individual on successive days and among different persons exposed to a particular air situation. Gastric complaints range from sensations of fullness or vague discomfort through gradations of nausea to vomiting and retching. Loss of appetite may occur. Sweating and pallor often are absent. Some complaining of being hot and dry seek cold air. Various head sensations are mentioned, including aching, dizziness, pressure and tightness. Many speak of a generalized feeling of nervousness. Some are unable to localize their symptoms beyond stating that they feel "sick all over." Pilots are least susceptible crew members, but, despite the advantages of over two hundred flying hours, about 1 in 8 suffered attacks subsequent to joining the unit. Symptoms occurred usually while riding as passenger or copilot and were overcome on taking over the controls. Approximately 80 per cent of men developing airsickness in the combat plane were occupants of the navigator's compartment, although this section of the aircraft approximates the center of gravity and is the area of least relative motion. Lack of opportunity for visual orientation may influence susceptibility in this section, for occupants at times avert or suppress sickness by moving forward to the pilot's compartment. Observations suggest that airsickness primarily is not a motion sickness but a true aeroneurosis. On this hypothesis a therapeutic approach was devised. Thirty-five crew personnel grounded for repeated severe airsickness were scheduled in small groups for daily flights of graded duration. Prior to take off, pentobarbital sodium 0.100 Gm. and atropine sulfate 0.0013 Gm. were administered orally to each man. On successive flights personnel were rotated as far as possible through different positions in the airplane. On reaching a stage in which a three hour period caused no distress, transfer to the combat plane was made and medication gradually eliminated. Ten men were restored to full flying status and have given no indication of relapse. Nine have improved to the point of being placed on crews on probationary status. Four were transferred prior to completion of treatment. Six showed no perceptible improvement.

Bacillary Dysentery in Army Camp.—Adams and Atwood give an account of their experience with the isolation and identification of pathogenic enteric organisms from the stools of patients admitted to the station hospital, Camp Claiborne, Louisiana, from September 1941 to October 1942 with illnesses diagnosed clinically as dysentery, diarrhea or gastroenteritis. Cultures were taken of approximately 2,000 stools from patients with diarrhea. From these cultures 642 strains of organisms considered to be pathogenic were isolated from 251 patients with definitely established dysentery. A member of the Shigella group was isolated from 226, or 90 per cent, of the patients. Of these, 178, or 70.9 per cent of the total, yielded Shigella paradysenteriae (Andrewes V-Z spectrum) and were benefited by therapy with a sulfonamide compound. Twenty, or 8 per cent, of the total number of patients yielded Shigella Newcastle and were probably benefited by treatment. Twenty-eight infections due to Shigella sonnei and Shigella alkalescens did not respond to chemotherapy. A member of the Salmonella group was recovered in 6 cases. An organism belonging to the paracolon group was recovered in 33 cases in which this organism was believed to be of pathologic significance.

Oral Hippuric Acid Test in Infective Hepatitis.—Gordon reports that between December 1941 and September 1942 168 cases of infective hepatitis were admitted to a hospital in the Middle East forces. Two fairly distinct types of onset were recognized: (1) cases with febrile attack and (2) cases without febrile attack. In the 88 patients with febrile attack the onset was usually sudden, often with shivering and occasionally with a rigor. Fever ranged from 100 to 102 F., the highest recorded temperature being 104 F. The pulse rate usually varied from 80 to 90 and often dropped to 50 or 60 when jaundice became established. Headache was noted in 85 per cent. Malaise, rarely amounting to lethargy, was almost constant. Two thirds complained of backache and/or pains in the limbs. Gastrointestinal symptoms were universal. The average duration of the prodromal stage before the appearance of jaundice was 5.8 days. In the 80 cases without a febrile attack the preicteric stage was of shorter duration, averaging 4.1 days. Gastrointestinal symptoms were evident from the first and, though similar to those in the "febrile" group, were not so constantly present. After the appearance of jaundice the physical findings and subsequent clinical course were almost identical in the two groups. The average duration of icterus was twenty-four days. The liver was palpable in 50 per cent of the cases. Gross hepatomegaly was associated with prolonged jaundice, and the larger the liver the longer was the duration of icterus. The diagnosis in the preicteric stage is often difficult and in many cases will remain uncertain until bile pigment appears in the urine. Hippuric acid tests for liver function by the oral method were performed in 14 cases when icterus was at about its height. Evidence of impaired function was found in all cases. Recovery of liver function (as measured by the hippuric acid test) appears to be slow. In the convalescent stage of the illness, when icterus had just disappeared from the skin but remained in the sclerotics, evidence of liver insufficiency was demonstrated in 19 (65 per cent) of the 29 cases tested. Second attacks appear to be no worse than the first.

 *Pulmonary Signs in Malaria. E. M. Stirk.—p. 272.

Pulmonary Signs in Malaria.—Stirk reports a feature of malaria which has been observed in an area in which malaria, sandfly fever and respiratory infections are common. It has been his experience that the initial symptoms in the three disease groups may be very similar until blood films have been taken to establish or eliminate the possibility of malaria. The author mentions 4 cases to illustrate this fact. He describes a case which demonstrates the development of an early pneumonia after the malarial pyrexia had been controlled. This case is important because it illustrates that sulfapyridine and quinine

are not incompatible when given concurrently. The author thinks that the association of bronchitis and incipient pneumonia with proved attacks of malaria is more common than medical writings suggest. In the region in which he made his observations approximately 10 per cent of the patients with malaria presented pulmonary symptoms.

 Value of Bronchoscopy in Bronchopulmonary Tuberculosis. M. D. Rodriguez D.—p. 77.

Acute Otitis Media in Children.—Latorre and Landa studied 143 cases of acute otitis media in children whose ages ranged from 1 month to 11 years. *Streptococcus hemolyticus* was found to be the commonest infective agent, being responsible for 89 cases (59.30 per cent) of the otitis media in this group. This organism was associated with the staphylococcus in 36 cases. Pneumococci were found in 32 cases (22.37 per cent). In the great majority of cases (78.32 per cent) otitis media healed without complications or sequelae in from five to twenty-five days. In 18 cases (12.58 per cent) the acute process was followed by chronic otitis. Of 4 cases in which mastoiditis developed, 2 responded well to medical treatment and 2 required surgical intervention. In 11 cases retroauricular subperiosteal abscesses formed. Bell's palsy in 1 case was promptly controlled by a mastoid operation. Meningeal and vascular involvement were not observed. There was no death. Treatment consisted, as a rule, in paracentesis, local heat, ear washes and nasal instillation. Sulfanilamide and sulfathiazole were used in 45 cases, of which 37 healed completely in an average period of twenty days and chronic otitis developed in 7. The results showed that sulfonamide treatment is not more effective in otitis media than the nonchemotherapeutic procedures used.

Revista de Tuberculosis, Havana

7:147-400 (April-June) 1943. Partial Index

- *Air Cysts of Lung in Children: Clinical, Roentgen and Anatomic Study. T. Valledor, E. Martel, R. Fuste and A. Fernandez Baltrons.—p. 147.
 *Acute Edema of Lung in Pulmonary Tuberculosis. A. Fernandez Conde, E. Alvarez Lastra and R. Meneses Mañas.—p. 282.

Cystic Disease of Lungs in Children.—Valledor and his collaborators report observations on 17 young children with cystic disease of the lungs. The majority of the patients were newborn infants and infants. There was neither syphilis nor tuberculosis in their family histories. A necropsy was performed on 3 patients. Cystic disease of the lung is a congenital malformation having its origin in a mesodermal hypoplasia of the bronchi and a zone of lung parenchyma. The latter remains in the stage of fetal development. Air cysts of the lung are always multiple, although in some cases apparently, but not really, solitary. The age at which the clinical symptoms appear is variable. Latent forms are rare. The cysts are frequently complicated by recurrent respiratory disease, which is controllable by early sulfonamide therapy. The most frequent clinical forms of the disease in children are those with recurrent attacks of more or less acute dyspnea, those with chronic or recurrent disease of the respiratory tract and those with pulmonary suppuration. The diagnosis of these types is confirmed by bronchography and tomography. The prognosis is grave. Lobectomy or pneumonectomy is the only effective therapy.

Acute Edema of Lung in Pulmonary Tuberculosis.—According to Fernandez Conde and his collaborators edema of the lung in pulmonary tuberculosis is rare. A man with bilateral pulmonary tuberculosis, while being hospitalized for observation, suddenly died in an attack of asphyxia. The post-mortem showed besides lesions of bilateral pulmonary tuberculosis acute edema of the lungs without involvement of any other organ. The authors believe that in pulmonary tuberculosis acute depression of the defense mechanisms with consequent loss of the immunoallergic balance is the cause of a perifocal edematous reaction of tuberculous nodules. Edema rapidly passes to the pulmonary alveoli because the pulmonary capillaries are hyperpermeable in pulmonary tuberculosis.

Book Notices

Managing Your Mind: You Can Change Human Nature. By S. H. Kralnes, M.D., and E. S. Thetford. Cloth. Price, \$2.75. Pp. 374. New York: Macmillan Company, 1943.

This is one of the better written self-help books. It presents and analyzes the difficulty which any one would meet in adjusting to his environment. The major thesis of the book is that "man is a total organism with both physical and psychological entities which are not separate." The authors feel that an individual to be in perfect health must have excellent physical health as well as sound mental health, which involves control of our emotional states. The entire book is given over to demonstrate the validity of the statement that one "can change one's mind." It is a detailed explanation of the technic whereby the external situation can be controlled by the individual, and it guarantees that the individual can learn to develop such control of mind, body and emotion that they will work together smoothly. They distinguish between emotional symptoms and physical symptoms. They feel that the individual must understand himself in terms of his elemental primary needs as well as in terms of the social demands which are made on him. The book is divided into eighteen chapters. A very clever device of using thought provoking questions brings out and develops the patient's self analysis and is used together with apt illustrations well within the range of the average person's experience. It is a safe book to put in the hands of a layman. It is definitely constructive and helpful to the reader to organize his thinking. The psychologic and physiologic background is pertinent as well as sound. The technics and facts are given and the various analytic terminology brought in, where necessary, to elaborate their explanations. They argue less by analogy than most books which are developing personal achievements. They use case history illustrations conservatively. It is particularly valuable to psychiatrists who may wish to give it to patients "to point up" their thinking and to open up new avenues for further analytic exploration. Its approach to the problem of personality problems is a positive one. It has much to offer any reader who wishes to change his habits of emotional thinking and reaction to achieve the goal of all, "happiness."

Experimental Surgery: A Laboratory Guide for Undergraduate Students. By J. M. McCaughan, B.S., M.D., Ph.D., Assistant Professor of Surgery, St. Louis University School of Medicine, St. Louis. Paper. Price, \$2. Pp. 82, with 32 illustrations. St. Louis: C. V. Mosby Company, 1943.

An experienced teacher of experimental surgery for undergraduate medical students has prepared a laboratory guide for a course in this field. The manual comprises an introduction setting forth the purpose of the course and general directions for the organization of an operating team, the preparation of instruments, drapes, suture material and anesthesia. Thirteen exercises, each consisting of a chapter, deal with technic for most of the major surgical procedures in the abdomen, in the thorax and on the nervous system—in short, the whole field of operative surgery. The author has effectively combined experimental physiology, pharmacology, pathology and surgical technic. At the end of each exercise there are a bibliography and a list of questions for discussion, an appropriate chart of the animal's condition during operation to be filled out, space for postoperative progress notes and blank space for the student to make additional notes of his own. The book is adequately illustrated by clear diagrammatic line drawings, figures and charts. By way of criticism certain features may be pointed out: The author has not included a number of the most recent advances in operative technic such as the so-called aseptic bowel anastomoses and improved gastrostomies; the problems of colon versus small bowel surgery are not emphasized; in some respects the academic treatment of the subject matter is overemphasized, as in the production of peritonitis where the student is directed to infect the peritoneal cavity with sponges dipped in cultures of *B. coli* (in the reviewer's opinion a more vivid procedure might be the production of a wound in the colon that is not repaired, or the smearing of the animal's own colon contents over the peritoneal cavity). The bibliographies, while adequate enough, include a large number of references to works published ten or more years ago. Among the questions to be pondered by the student are a number of problems which are still quite

controversial among experienced surgeons. The merits of this work, however, outweigh its weaknesses, and the author is to be commended for his efforts in producing a formal plan and guide for the student in this subject. The manual is printed in mimeograph form and is conveniently bound loose leaf to permit the addition of notes and other subject matter.

Health Practice Indices. Compiled from the Evaluation Schedules Submitted for the National Health Honor Roll for the Years 1941 and 1942. Prepared by the Sub-Committee on Manual and Appraisal of Local Health Work for the Committee on Administrative Practice of the American Public Health Association. Paper. Pp. 73, with illustrations. New York, [n. d.].

This is a graphic representation by means of bar charts of various public health procedures based on actual practice in a group of reporting cities, counties and health districts. It is compiled from the evaluation schedules submitted for the National Health Honor Roll of the United States Chamber of Commerce Interchamber Health Contest. It contains charts indicating the prevalence of standard practice in communicable disease control, tuberculosis and venereal disease control work, maternal, infant, preschool and school health practices and sanitation, food control and milk control.

The information for a given activity, such as percentage of antepartum cases known to have medical supervision, is portrayed with the most favorable reports at the top and the others ranged in decreasing order toward the bottom of a horizontal bar chart. In this particular activity the cities in the upper quartile range from almost 100 per cent down to 80 per cent of antepartum cases known to have had medical supervision. The percentages in the second quartile range from 79 to 66. In the third quartile the range is from 55 to 18 and in the lower quartile from 18 to 2 or 3. In this particular instance approximately 20 per cent of the communities reporting give no data or incomplete data.

The use of such a chart to the local health administrator is by comparing his own performance with that of others through finding its position in the chart. If he is in the upper quartile he is among the best. If he is in the lower quartile or below the base among those having no data or inadequate data his community is in serious need of improvement.

Throughout the book the charts indicate that few of the public health procedures are universally well performed. Few of the best organized health departments in the nation on which these graphs are based will be found approaching 100 per cent. The graphs showing best performance are those in the oldest field of public health, namely the various branches of sanitation. Perhaps these charts contain a suggestion that before governmental medicine is extended into the field of medical care there is room for vast improvement in accepted standard public health procedures.

Fifty Years of Service: A History of the Mary Hitchcock Memorial Hospital. By Leon B. Richardson of the Board of Trustees. Boards. Pp. 80, with illustrations. Hanover, New Hampshire, [n. d.].

This book, which commemorates the completion of fifty years of service, is a history of the Mary Hitchcock Memorial Hospital since its establishment in 1893. It is a story of the growth and development of an institution, its organization and management, financial aspects, community responsibility and support, expansions and readjustments, scope of hospital service, educational activities and other functions. These factors have been described in a clear and effective manner in relation to five separate administrative periods through which the hospital has passed. The author also reviews the present needs of the institution and anticipates with confidence that in a community of resourceful and public spirited citizens the hospital will have little difficulty in meeting whatever requirements the future may impose.

Authority in Medicine: Old and New. By Major Greenwood, D.Sc., F.R.C.P., F.R.S., Professor of Epidemiology and Vital Statistics in the University of London. Boards. Price, 40 cents. New York: Macmillan Company; Cambridge: University Press, 1943.

This Linacre lecture concerns principally the extent to which the writings of Galen dominated medicine for many years and moves on to a consideration of the manner in which research goes beyond authority. The conclusion is a testimony to Walter M. Fletcher, who first headed the British Medical Research Council.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THIS WILL BE OMITTED ON REQUEST.

MORPHINE AND SHOCK

To the Editor.—In the *Bulletin of the American College of Surgeons* 28:109 (June) 1943 in the article "The Injured in Combat Zones" it is emphasized that morphine should not be given in head injuries; and in Dean Lewis's *Practice of Surgery* (vol. XII, chapter 1, p. 281) I find that, in the treatment of shock complicating cranial injuries, liberal doses of morphine should be given. Why do some authors advise against the use of morphine in the treatment of shock accompanying head injuries? Is it because of the depressive action to the respiratory centers? Doesn't the good effect of morphine in shock justify its use in spite of its ill effect on the respiratory centers?

Albert Borges, M.D., Endicott, N. Y.

ANSWER.—The hypodermic administration of morphine in the treatment of traumatic shock following head injury has its advocates and its opponents. By reason of the potent depressive action of the drug on the respiratory center, the use of liberal doses of morphine should be formally contraindicated in any type of severe shock, whether involving craniocerebral injury or not. The available evidence indicates that in head injury, unless given in minimal doses, morphine contributes to aggravation of anoxia and death. On the basis of careful work, Gurdjian, Webster and Sprunk (*Studies of the Spinal Fluid in Cases of Injury to the Head: Effect of Drainage, Isotonic Fluids, Morphine and Soluble Phenobarbital*, U. S. P., on Cerebrospinal Fluid Pressure, *Arch. Neurol. & Psychiat.* 42:92 [July] 1939) emphasized the dangers attendant on the use of morphine in cranial injury and concluded that this drug should hardly ever be used in the treatment of this condition, especially in severe cases, not only because it masks symptoms and depresses respiration, but because it produces a tremendous rise in cerebrospinal fluid pressure which may endanger the life of the patient. Phenobarbital, which is much less harmful and fairly effective in quieting these patients, may be advantageously substituted for morphine.

OXYGEN ADMINISTRATION WITH B. L. B. FACE MASK

To the Editor.—I should like to have some information on the administration of oxygen to patients unconscious from head injuries complicated by other injuries. I use a Boothby-Lovelace-Bulbulian face mask with 100 per cent oxygen at the rate of 6 to 8 liters per minute. The percentage of oxygen reaching the alveoli is one of the points in doubt. With the patient breathing about 36 to 40 times a minute and the mask held in place by an attendant, what is the probable percentage of oxygen reaching the alveoli? Are there any dangers associated with prolonged administration of oxygen under such circumstances? What percentage of oxygen administered over a prolonged period can cause damage to pulmonary tissue? Can such a percentage be reached by the use of a B. L. B. mask? References or authorities cited would be helpful.

Captain, M. C., A. U. S.

ANSWER.—In the use of oxygen equipment, if 100 per cent oxygen is inhaled it will be diluted by water vapor and carbon dioxide before reaching the alveoli. If the Boothby-Lovelace-Bulbulian face mask is used and the reservoir bag does not collapse during any inspiration, except for the dilution stated, for all practical purposes the only other gas in the alveoli will be oxygen. If during inspiration the reservoir bag collapses, the resistance of the sponge rubber disks will be overcome by air drawn in to dilute the oxygen. The amount of this dilution, i. e. the point during inspiration at which the bag collapses, will depend on the flow from the oxygen regulator and the minute respiratory volume of the patient. In a patient breathing from 36 to 40 times a minute a flow of 6 to 8 liters per minute would not keep the bag from collapsing, depending, however, on the depth of each respiration. With a respiratory rate of 40 times a minute assuming perhaps 400 cc. tidal volume, a flow of over 16 liters per minute would be required to maintain 100 per cent oxygen in the inspired air. In the case cited it would be estimated that approximately 40 to 50 per cent oxygen would be added to the air inhaled. Breathing of 100 per cent oxygen over prolonged periods, twelve to twenty-four hours, by normal persons does not cause appreciable damage of pulmonary tissues at atmospheric pressure or less. When using a mask, essentially 100 per cent oxygen may be used indefinitely without fear of damage. It is suggested that flows be turned to 10 or 12 liters per minute if high oxygen concentrations are required for patients with rapid respiration.

HEADACHES, DIPLOPIA AND FIXED PUPIL

To the Editor.—Please give me prognosis and treatment, if any, in the following case. A man aged 29 had a fractured skull in 1933 and was hospitalized for sixty-eight days. He has since been having severe frontal headaches and occasional diplopia at night, which is relieved by analgesics. In 1938 he received a slight brain concussion but was not hospitalized or put at bed rest. He has been refused by the Army and the Merchant Marine because of lack of any pupillary reaction to light. Examination at this time reveals blood pressure 120/80, weight 142 pounds (64 Kg.), height 5 feet 5 inches (165 cm.); examination of ear, nose and throat negative. The pupils are clear and regular, are of normal size, and show no reaction to light or in accommodation, the fundi are small but otherwise normal. There are no cranial nerve disturbances, the chest is clear, the heart normal, rate 76 per minute, rhythm regular. There are no murmurs or enlargements. The abdomen and extremities are normal. The abdominal and cremasteric reflexes are normal, deep reflexes are not present; the Babinski reflex is negative on both sides. The Wassermann test is negative; no spinal Wassermann test has been made.

M.D., New York

ANSWER.—A fractured skull of ten years ago would have no bearing on the patient's present headaches and double vision. Lack of pupillary response suggests syphilis in spite of the negative Wassermann reaction. A spinal fluid Wassermann test would probably be in order with examination of the pressure at the time. A brain tumor is the only other possibility.

INDUCTION OF JAUNDICE

To the Editor.—A selectee has been deferred from military service on account of "subclinical jaundice." The question of the legitimacy of this claim has come up, and I wish to know whether it is possible for the condition "subclinical jaundice" to be self induced; that is, whether it is possible for a person to take bile salts by injection or by mouth or to raise his icterus index above normal by any other means in order to receive this classification.

M.D., North Carolina

ANSWER.—It is quite possible for jaundice to be self induced. Many of the coal tar derivatives may cause mild degrees of jaundice in sensitive persons. The following are but a few of the many drugs which are known to cause jaundice: chloroform, toluene, benzene, carbon tetrachloride, dinitrophenol, cm-chlophen and arspenamine. During treatment of malaria with atabrine it is not uncommon to see jaundice develop. Bile salts are definitely hemolytic and may cause jaundice if injected into the blood stream, but it is not likely that it could be controlled so as to produce mild jaundice without causing other toxic symptoms. Amounts possible to be taken by mouth will not cause a normal person to have jaundice. It is well known that the determination of the icterus index (Meulengracht test) may give high values in carotenemia, and the ingestion of large amounts of carrots could influence the test to a degree sufficient to suggest subclinical jaundice.

STIMULATING DOSE OF TOXOID AFTER EXPOSURE TO DIPHTHERIA

To the Editor.—My attention has been called to the fact that some physicians give a stimulating dose of diphtheria toxoid to persons who have been exposed to diphtheria with the understanding that this would be sufficient to increase the antibody content for protection. I should like to know whether this practice is feasible.

M.D., Louisiana

ANSWER.—If some years previously the patient had been inoculated with diphtheria toxoid followed by a negative Schick test, it would be feasible to administer a stimulating dose of diphtheria toxoid if exposure to diphtheria was anticipated as a possibility. But if the person had never been immunized and was known to be susceptible, the injection of toxoid at the time of exposure to diphtheria could not be relied on for protection. Under the latter circumstances diphtheria antitoxin would be indicated. Those who are Schick negative when exposed to diphtheria should not require either toxoid or diphtheria antitoxin as a prophylactic.

TOXIC REACTION TO SULFAMERAZINE

To the Editor.—I have been neglecting to report a case of toxic reaction to sulfamerazine. On Oct. 13, 1943 a girl aged 13 was seen who had sore throat and fever. She was given sulfamerazine at the rate of 1 Gm. every six hours until a total of 9 Gm. had been administered. This medication was discontinued two days later because it seemed to make her feel worse. She complained of pain in the flanks which the family considered possible appendicitis. I saw her on October 16, at which time she had a normal temperature and complained of pain in both flanks and both sides of the abdomen (not appendicitis). Urinary output decreased, becoming scanty and bloody on October 17. On the 18th her condition was good, the urine specimen contained both gross and microscopic blood (no possibility of menstrual contamination). An uneventful recovery was made. I thought this case should be reported because the medicine was detailed to us here as peculiarly free of danger to the kidneys.

THE DIFFICULTY OF EVALUATING DRUG TREATMENT IN SURGICAL INFECTIONS

FRANK LAMONT MELENEY, M.D.

Associate Professor of Clinical Surgery, Columbia University
College of Physicians and Surgeons

NLW YORK

The sulfonamides have been called the "miracle" drugs, and it is true that certain infections respond dramatically to their use. However, one finds that there are many conditions in which they cannot perform miracles and where their benefit is questionable. In fact, many cases have been reported of disastrous effects. Now penicillin comes to the fore and is called the "wonder" drug. To what limits are these new agents "miracle" or "wonder" drugs? What is the basis for these popular enthusiasms? To what degree are these misconceptions in the minds of the members of the medical profession? Are our own medical reports at fault? These questions need answers.

We have now had five or six years' experience with the sulfonamide drugs in various types of infections, and it ought to be possible to outline their indications and limitations.

The unquestioned value of sulfanilamide was clearly proved when hemolytic streptococcus meningitis responded to its use, because formerly that infection was almost invariably fatal. Furthermore, not only did hemolytic streptococcus septicemia, with a former mortality ranging around 50 per cent, show a significant drop in this figure, but the disease itself virtually disappeared from our hospitals. That is an established fact which is generally recognized.

It was inevitable that sulfanilamide should be used in all other kinds of infections as soon as its relative safety, cheapness and availability had been demonstrated. However, it was not long before sulfanilamide was being used indiscriminately by doctors and even by patients themselves with or without the advice of corner druggists or well meaning friends. It was then found that it was not the panacea that it had been thought to be but had a selective action for certain types of bacteria. The necessity for determining the bacterial nature of every infection then became apparent, and yet we still find doctors using the therapeutic test and not only running the risk of toxicity but losing the opportunity for prompt, specific treatment which might be instituted by an exact knowledge of the bacterial etiology of the infection in hand. The same thing is true for the other sulfonamides.

In the last five years many reports have appeared in the literature purporting to show the value of the newer chemotherapeutic agents in all kinds of infections,

but few of these reports have included observations of controls. In some of these reports individual cases have been described in which it seemed to the observer that the drug accomplished something which would not have been achieved without the drug. The only control was the previous treatment of the case itself. In other papers the results in a series of cases have been compared with the author's previous experience. But in most instances the controls have not been run parallel with the treated cases under the same conditions.

It would seem obvious that a series of cases under careful management and close observation cannot be compared with another series in a previous period of time not carefully studied and not under the same conditions of management. Furthermore, many other factors come into play year after year which materially serve to lessen the incidence or shorten the course of infection. For examples I need mention only such devices as the Miller-Abbott tube in peritonitis, the steadily increasing knowledge of the importance of electrolyte and protein balance and nutrition in combating infection. The seasonal variations from month to month or year to year in the virulence of organisms is too well known to warrant more than a reminder.

Many of the favorable reports of the action of the sulfonamide drugs, for example, have dealt with medical infections. In surgical infections which have in the past responded in a measure to the surgical procedure the results of an associated drug therapy have perhaps been more open to question, and it is with these that I wish to deal in this paper. Let me first point out some important differences between surgical infections and medical infections.

A COMPARISON OF "MEDICAL" AND "SURGICAL" INFECTIONS

1. Infections are considered surgical if they can be controlled by an operative procedure. Surgical infections are usually characterized either by a localized breakdown of tissue or by a collection of purulent exudate or are those associated with some kind of a wound. The surgical procedure may be a complete or partial removal of the infected tissue or it may be an incision or an aspiration which drains off or removes the liquefied tissue or purulent exudate. A medical infection, on the other hand, is a localized or generalized diffuse cellulitis with little or no breakdown of tissue or little or no gross localized confined exudation of leukocytes.

2. If a patient is to recover from a surgical infection there must usually be either a spontaneous evacuation or a surgical removal of the dead tissue or purulent exudate. If there is an operative procedure there must always be a scar resulting from the healing process. If a patient recovers from a medical infection the involved tissue or organ is restored practically to

normal with little or no gross evidence of scarring of that organ. (When tuberculous lesions break down, they frequently become surgical.)

3. In surgical infections the repair of the wound and the abscess cavity frequently demands greater resources of nutritive elements than for the restoration of tissues in medical infections in which they have not been injured.

4. Surgical infections are caused by the pyogenic or necrotizing organisms, and frequently there is a variety of species taking part in the process. This is particularly true of infected wounds. Medical infections are usually caused by a single organism or virus, although surface infections such as enteritis or colitis may permit the activity of secondary contaminants.

5. The wall of an abscess is made up of necrotic tissues and thrombosed blood vessels which may prevent immune elements or medication in the blood from reaching the focus where the organisms are living and carrying on their metabolic processes. In medical infections patent or even dilated blood vessels course through the inflamed tissue carrying any immune substance or medication which may be present in the blood, and these have a better chance of coming into close contact with the infecting organisms than in surgical infections. Furthermore there is evidence that dead tissue inactivates many of the antibacterial agents which may be applied to surface wounds or reach a focus through the blood stream.

6. On the other hand it should be noted that with surgical infections after recovery there is little evidence that any general immune reactions have developed in the course of the disease. The control of the infection may be accomplished by some "immune" reaction of the local tissues, but there is no evidence of lasting immunity. With many medical infections there is evidence of the development of immune substances which can sometimes be detected in the blood in the early stages of the infection. Frequently they play a critical role in the recovery from the disease and provide a lasting protection against it for the rest of the patient's natural life.

7. Perhaps the most important difference between medical and surgical infections is that the former are not benefited but are made worse by incision while the latter are usually made better. This is probably due primarily to the removal of dead tissue.

And yet in the early stages the surgical inflammation, which later breaks down with necrosis of tissue and purulent exudate, is similar to a medical inflammation. If a drug can be given in the earliest stages of an infection before there has been any breakdown of tissue, it seems obvious that it should have a greater effect than if given after the infection has gained a foothold and has gone on to the necrotizing stage. Obviously also the larger the dose of medicine that can be given within the low limits of toxicity, the more effective it should be. On the other hand the best results to be expected from a surgical procedure are frequently not obtained by the earliest and most extensive operation. It is true that with contaminated accidental wounds or war wounds early surgery is of the greatest importance as a prophylactic measure against infection. However, in spontaneous infections a delay in the operative procedure may be the best treatment, and the proper timing may be more important than the nature of the procedure itself.

If there has been an accidental wound or a war wound (and these wounds are always contaminated by organisms) or if there has been a surgical procedure in a spontaneous infection, the opportunity is given for the local application of the drug to the surface of the wound or infected tissues as well as for the general administration of it, while no such opportunity is offered in medical infection, except for certain involvement of visible mucous membranes such as tonsillitis, conjunctivitis, urethritis or vaginitis.

If we are going to appraise drugs in surgical infections properly, all of these, various factors must be weighed and measured. Any drug will alter the normal course of an infection to the extent to which it can slow down, either directly or indirectly, the growth or metabolism or the spread of the causative organism. The sulfonamides and penicillin seem to modify the natural course of certain infections and have no effect on others. We are in the process of finding out what their indications and limitations are, and the problem must be studied carefully and methodically and not with prejudice.

How then can drugs be appraised in the treatment of surgical infections? This question must be considered in two categories: prophylactic and therapeutic. Prophylactic treatment may be applied to those conditions which are likely to produce infections. First, the ones of greatest interest at present are the war wounds and burns. Second, and closely similar to these in many respects, are the civilian accidental wounds and burns. A third group consists of operative wounds in contaminated areas, for example operations on the alimentary tract, particularly the esophagus, lower ileum and colon.

PROPHYLACTIC STUDIES

In the prophylactic appraisal of drugs, control series are absolutely essential. One must know the incidence, severity and duration of infection in drug treated cases and in a parallel series treated in exactly the same way without the drug. Differences in percentage of infections between the two series must fulfil the requirements of the formulas of the biostatisticians in order to minimize the possibility of chance being responsible for those differences.

It is essential also that the control series be strictly comparable with the treated series. In order to be certain of this it is necessary to record all the factors in the individual cases which may play a role either in favoring or in minimizing the development of an infection. Then all the cases which present each factor may be grouped together and contrasted with those in which that factor is absent. Within those contrasting groups the controls may then be compared with the treated cases. This is the method of cross tabulation.

For example, in accidental wounds or war wounds important factors which play a role in the development of infection are a short or a long interval of time between the accident and the operation, maximum or minimum gross contamination, maximum or minimum tissue damage and complete or incomplete débridement. In order that the presence or absence of these factors may be recorded in every case which is studied, it is necessary to employ case summary sheets on which these data are listed. To facilitate the analysis of these data, these summary sheets may be so arranged that the data can be transferred to punch cards. Then the incidence, severity and duration of the infection can be readily determined for each group of major factors. While

it is true that many factors will be operating in a given case, by multiple groupings of the cases according to the presence of a common factor as compared with its absence or antithesis, by cross tabulations, some indication may be given of the relative importance of these factors.

The biostatisticians tell us that when there is a multiplicity of factors operating in any given situation the importance of any single factor may be hidden or lost sight of, but if any single factor consistently stands out its importance is thereby demonstrated.

A study of civilian accidental wounds of the soft parts, compound fractures and burns, recently reported,¹ has been going on under the direction of the Subcommittee on Surgical Infections of the National Research Council in seven clinical and laboratory units scattered over the country. An appraisal has been made of the sulfonamides in the form of sulfadiazine for general administration either alone or combined with sulfanilamide or equal parts of sulfanilamide and sulfadiazine locally. From a study of our data we have found no indication that sulfonamides used in this way prevent the development of local infection, although they apparently prevent the general spread of infection and cut down the mortality. Four of the seven units which have carried out this study are now proceeding to the appraisal of penicillin and other promising agents to see if something cannot be found to cut down materially the incidence of infection in these accidental wounds. Similar studies could and should be carried out by investigating units at the front hospitals. Likewise, similar studies should be carried out in a series of contaminated operative wounds.

Let me emphasize again, however, (1) the necessity of having parallel alternating unselected, untreated controls under the same conditions as the treated cases, (2) the necessity for uniformity of study by the use of summary sheets, (3) the grouping of cases with a common factor, (4) the analysis of data by cross tabulations and (5) the application of the criteria of significance required by competent biostatisticians.

In prophylactic studies of wound infection the following factors may play a role either in favoring or in minimizing the incidence of infection, and the appraisal of drug treatment must be considered in the light of these factors and their interplay:

1. First aid treatment before hospital admission.
2. Age and basic nutrition and condition of the patient on admission.
3. Duration of time between injury and hospital admission and operation.
4. Local and general medication before hospital admission and operation.
5. Kind, size, depth and location of the wound.
6. Degree of gross contamination and tissue damage.
7. Nature and extent of bacterial contamination.
8. Method and completeness of excision of damaged tissue.
9. Duration of operation and wound irrigation.
10. Methods of wound repair, drainage and closure.
11. Immobilization of the part and frequency of dressings.
12. Local and general medication during and after operation.
13. Measures used to prevent secondary contamination.

THERAPEUTIC STUDIES

When an attempt is made to appraise the value of drugs in established surgical infections, the problem becomes still more difficult and it must be approached

in a somewhat different way. The most important differences between prophylactic treatment and therapeutic treatment are due to the element of time. In prophylactic cases there is a fixed starting point—the moment of the injury in war wounds, the time of the accident in civilian cases, the period of operation on contaminated regions. In established infections the period of time during which the organisms have had a chance to invade the body may vary from a few hours to several years.

This covers the whole range of acute and chronic infections. While there is no sharp line between them, it is profitable to make a distinction between acute and chronic infections because there are certain factors operating in one group and not in the other. For example in acute surgical infections there may be a period in which treatment can be instituted before there is a breakdown of tissue. This gives the best opportunity for a drug to work if it is going to do so. Surgery in many cases has not been done when the patient presents himself for treatment; perhaps it should be delayed pending localization; possibly it may be obviated altogether. On the other hand a chronic surgical infection in most cases has had not one but many forms of treatment, often including several operative procedures, there is already a breakdown of tissue and the chances of drug alone being effective obviating surgical procedure is often remote. Furthermore in acute, spontaneous surgical infections there is usually a single organism operating, while in chronic infections there is usually a host of secondary invaders that must be dealt with. In acute surgical infections the patient is frequently in excellent general physical condition, while in chronic infections the nutritional status of the patient is almost always seriously altered and the blood volume, the red cells, the hemoglobin, the plasma protein and other blood elements may have changed considerably.

For these and other reasons the number of factors in established infections which must be considered are much more numerous than in prophylactic studies. In certain acute surgical infections controls can be studied, but in chronic cases it is much more difficult to line up a control series. One must either (I) let the case itself, in its previous treatment, be the control or (II) show some results in the drug treated cases not previously seen in our surgical experience.

I. Examples of the case itself in its previous course being the control may be briefly illustrated by the following cases:

A. Acute infections. 1. A boy with a boil on his leg struck his hip while sliding to third base. That evening his fellows threw him in a lake. At midnight he had a chill followed by fever of 103 F. His blood culture revealed hemolytic *Staphylococcus aureus*. Sulfathiazole and sulfadiazine for a week failed to affect the course of the disease. Pain and swelling developed in the right buttock. Incision of the buttock abscess was of only temporary benefit. Penicillin was given and his temperature fell in twenty-four hours. Blood culture became sterile but x-ray examination showed progressive destruction of the ilium. All local signs subsided and he was sent to a convalescent home. Fever recurred and a tender mass developed on the inner surface of the ilium. X-ray examination revealed further destruction of the ilium and the sacroiliac joint. Another course of intramuscular penicillin was started and continued for ten days. All symptoms and signs disappeared and did not recur. X-ray examination revealed progressive reconstruction of the bone.

1. Ann. Surg. 118: 171-186, 1943.

2. A patient with a cellulitis of the face starting with a furuncle of the chin had a spiking daily temperature of 105 and 106 F. The blood culture revealed hemolytic *Staphylococcus aureus*. The swelling of the face closed the eyes and in the neck caused progressive difficulty in swallowing and breathing. Incisions were made in softened areas. *Staphylococcus antitoxin*, neoparsphenamine and other drugs failed, and the outlook seemed hopeless. She was then given *staphylococcus bacteriophage* intravenously in increasing doses, and within twenty-four hours the breathing became easier, swallowing was tolerable, the temperature fell and the blood culture became sterile. In four days it was obvious that she was out of danger.

B. *Chronic infections*. 1. The abdominal wound became infected following a hysterectomy; the infection spread and failed to respond to various antiseptics. Gradually an ulcer formed with undermined margins. Several attempts were made to control the infection by excision of the lesion. The temperature ranged to 101-102 F. daily. Then the ulcer measured 18 by 20 cm., with undermining in all directions 8 to 12 cm. farther. It was finally recognized as a chronic, undermining, burrowing ulcer and yielded on anaerobic culture the microaerophilic hemolytic streptococcus. It was then treated with zinc peroxide suspension. Promptly the fever subsided. The undermined margins began to heal down and it was soon possible to graft the defect successfully. Three days after the zinc peroxide was started, the microaerophilic hemolytic streptococcus was not found in the cultures but in its place a green streptococcus which did not interfere with wound healing.

2. Two years before admission, a patient had had an attack of chills and fever followed by pain in the lower right part of the chest and the right upper quadrant of the abdomen. He was incapacitated for a month and then returned to work but continued to have intermittent pain in the region of the right costal margin radiating to the shoulder and occasionally periods of mild jaundice. The pain increased in severity until three weeks before admission, when malaise developed followed by a severe chill. On examination a large, tender liver was found and a high right diaphragm. The temperature ranged from 99 to 102 F. Liver damage was indicated by function tests, high phosphatase and inverted albumin-globulin ratio. Amebas were found in the stools. A diagnosis of amebic abscess of the liver was made. The patient was put on a course of emetine and iodoxyquinoline sulfonic acid for ten days. The temperature fell in two days. The liver decreased in size. Amebas disappeared from the stools, and the patient remained asymptomatic.

In this brief recital of actual cases there seems to be little doubt about the value of the therapeutic agents. But even such cases must be multiplied many times and the results repeatedly confirmed to rule out the possibility of chance. If, however, in these cases the improvement had been a matter of weeks, or months rather than hours or days, the value of the therapeutic agent would have been questionable. So the time factor must be considered in the evaluation of the drug.

II. Cases showing results not previously seen in our surgical experience may be divided into several groups, as follows:

A. Those in which surgical procedures are obviated entirely.

B. Those in which surgery may be more limited or conservative than usual.

C. Those in which surgery is necessary but in which the healing time is definitely shorter than usual.

D. Those in which surgery is performed but closure of the wound may be safely done either primarily or within a few days.

The goal of the surgeon in his battle against infections is to prevent contaminating organisms from gaining a foothold in the body or to stop promptly the

activity of organisms which have already gained a foothold when the case comes under his observation. If this can be done in the early stages before there has been a breakdown, surgery may be obviated. If this can be done by the use of a drug in cases which in our experience always go on to necrosis without the drug, we can be certain that the drug was effective in those cases. It is even more striking if surgery is obviated by the use of drugs after the breakdown has taken place, i. e. if there is a resolution of the inflammatory process and an absorption of localized exudate without the aid of surgery.

A. Infections which in the natural course of events become surgical by virtue of a characteristic local breakdown of tissue or collection of purulent exudate are in the early stages simply diffuse cellulitis of limited extent. The breakdown may come early or late, depending on the variety and virulence of the species of the causative organism and the tissues involved.

Examples of such a course of events may be given in the following brief abstracts:

I. *Acute infections*. (a) A boy complained of a sudden onset of chills and fever of 105 F. with pain in the region of the great trochanter of the right hip but was found to have free motion of the joint. The blood culture was positive for hemolytic *Staphylococcus aureus* and he was given penicillin in large doses intramuscularly. The temperature fell abruptly but the local process remained painful for several days. It gradually subsided, but in the course of time x-ray examination showed some destruction of bone in the region of the great trochanter. This did not spread, however, and gradually the area of destruction was reconstructed without the necessity for surgery, which ordinarily would have been required.

(b) A mechanic had a collar button abscess of the hand, with a small superficial blister and a small opening through the skin into a larger cavity beneath the skin. Formerly such a lesion invariably required an incision into the deep cavity. The lesion was caused by a hemolytic *Staphylococcus aureus* susceptible to a potent bacteriophage, which by simple daily instillations into the deep cavity invoked a local subsidence of the process without the necessity for surgery.

II. *Chronic infections*. (a) A woman of middle age had a large ulcer of the leg with a shaggy, pale, granulating base and undermined rolled in skin margins infected with a mixture of hemolytic streptococcus, hemolytic *Staphylococcus aureus* and *Bacillus pyocyaneus*. The base was indurated, and the surgeon planned to excise it to get rid of the infection and establish a relatively normal base. Instead the wound was sprayed daily with sodium sulfadiazine powder. Exudate diminished, the smears and cultures showed a rapidly diminishing bacterial flora, first the hemolytic streptococcus disappeared and then the pyocyaneus, and lastly the staphylococcus ceased to be active. The edges sealed down, new epithelium grew in and the wound became amenable to grafting.

(b) A bartender struck a drunken patron and sustained a tooth laceration of the back of the hand. A foul smelling infection developed in the course of a few days. Cultures revealed spirochetes, fusiform bacilli and anaerobic streptococci. The first metacarpophalangeal joint was threatened. Daily application of zinc peroxide resulted in a rapid subsidence of the inflammation and disappearance of the organisms. Without this response, invasion of the joint would probably have occurred and amputation would probably have been required.

B. In certain surgical infections past experience has shown that limited incision or excision has been ineffective and it has been necessary to incise beyond the involved area or excise the lesion by a wide margin. It has been found, however, that with the use of certain drugs a more conservative operative procedure may be effective. There is, of course, some difficulty in

judging such cases and in being certain that the procedure is more limited than would otherwise have been necessary. Clearcut examples, however, are found in the following cases:

I. *Acute infection.* A sudden onset of painful swelling of the leg extending to the thigh in forty-eight hours showed the characteristic area of bluish discoloration and bullous formation pathognomonic for hemolytic streptococcus gangrene. This area went on in four or five days to frank gangrene. In the natural course of events it is necessary to make multiple incisions extending up beyond the area of swelling into normal tissues, but in this case the gangrenous area was excised and sulfadiazine was given by mouth. The process came to a standstill with steady and fairly rapid resolution. The skin defect was then covered with a graft.

II. *Chronic infection.* In a typical case of progressive bacterial synergistic gangrene of the skin of the abdominal wall there was a large ulcer with steadily spreading, intensely painful gangrenous margin surrounded by a red raised purple zone and outside of that a zone of erythema of varying width. In the natural course of events this process can be stopped only by wide excision of the whole lesion well beyond the zone of erythema. In this case, however, a more limited excision was done at the outer margin of the purple zone followed by the application of zinc peroxide. This controlled the infection, and the favorable effect of the drug as an adjuvant to surgery seemed fairly obvious.

C. In the third group in which surgery is necessary but in which the healing time is definitely shorter than usual, the effect of drug therapy is much more difficult to evaluate and a parallel series of control cases is required to make the demonstration convincing. The time for healing is dependent not only on the control of the infection but on the original extent of the lesion, the amount of tissue injury already done and on many other factors which should be taken into consideration and recorded. Added data to indicate the control of infection are obtained by making a quantitative and qualitative study of the bacterial flora before and at frequent intervals after the surgical procedure, both in cases in which there is an accompanying administration of the drug and in the controls. Cases of this group are abstracted:

I. *Acute infection.* A young man developed a 10 cm. abscess of the anterior portion of the perineum extending up on the scrotum, which on culture yielded a hemolytic *Staphylococcus aureus*. Through the central opening potent staphylococcus bacteriophage was instilled and a silk drain inserted. There was rapid subsidence of pain, swelling and redness. The drain released copious quantities of pus, and this was the only surgical procedure. The process completely subsided, and the wound was closed in six days.

II. *Chronic infection.* A boy of 14 entered the hospital with a six weeks history of a painful swollen knee. X-ray examination revealed an abscess in the external condyle of the femur. Aspiration of the knee yielded thin fluid; 5,000 units of penicillin was instilled. The joint fluid revealed hemolytic *Staphylococcus aureus*. Next day the joint swelling was less. The bone cavity was unroofed and the cavity tamponed with China silk and fine gauze packing wet with 5,000 units of penicillin. The packing was renewed and 5,000 units instilled daily. The cavity filled rapidly with granulation tissue and healing was complete. The joint was not opened or aspirated again and returned to normal function.

D. In the last group, in which a primary or early secondary closure is done with the aid of drug in conditions which ordinarily would not permit such procedures, care must be taken in evaluation of the role played by the drug. For some time it has been recog-

nized as a sound procedure to close the wound primarily after the removal of an acutely inflamed or gangrenous appendix but not after a nephrectomy for an abscessed kidney. Some surgeons have advocated and practiced closure of the wound after excision of a gangrenous or suppurative gallbladder. Many have tried it with occasional success immediately after the saucerization of a chronic osteomyelitis. If any large series of these cases is going to be studied to evaluate the use of associated drug, to be convincing it must be studied in conjunction with a series of controls under similar conditions without drug. In this group it should be possible to run a parallel series of controls. Incision into an abscess for the purpose of evacuating pus seldom if ever permits an immediate primary closure of the wound, because besides the freely flowing pus there is usually adherent slough, which has to separate and come away before healing can take place. Any attempt at closure is followed by a breakdown of the wound. If any drug treatment would permit such a primary closure, it would be extraordinary and therefore its value unquestionable. However, secondary closure of such wounds, after the separation of the slough, has been successfully practiced and any convincing evaluation of the role of an associated drug therapy would have to show a significantly shorter time for the interval between incision and closure or a shorter healing time.

In cases permitting early secondary closure an opportunity is given also for a comparison of the rapidity of the diminution or disappearance of the organisms involved in the infection in drug treated cases and in controls. It is probable that this should be the criterion by which to determine the safe and proper time for closure. An illustrative case follows:

A subacute infection. A young cadet on a transatlantic steamer scratched his left index finger while cleaning an engine head. An indolent infection developed, with gangrene of the skin on the radial side of the distal phalanx. It smoldered for a month, gradually spreading. Then an area of gangrene appeared on the dorsum of the first interphalangeal knuckle, exposing the tendon and joint. The infection dissolved the extensor tendon and the first interphalangeal joint. The proximal phalanx and hand became swollen red, and tender. The temperature rose to 104 F. Cultures yielded both the hemolytic streptococcus* and *Staphylococcus aureus* but no anaerobes. The patient was given penicillin generally and locally. The finger was amputated, the distal two phalanges being removed, a long anterior flap being left. Stitches were placed for delayed primary closure, which was done three days after the amputation, when the cultures showed only a few staphylococci. General penicillin being continued for ten days, the wound healed without any clinical evidence of infection.

In established surgical infections the following factors may play a role in maintaining or resolving the infection, and any appraisal of drug treatment must be made in the light of these factors. There are some differences between acute and chronic infections as indicated.

1. Diagnosis of infection, serious or trivial, and location of lesion (acute and chronic).
2. Duration of illness in hours or days (acute) or months or years (chronic).
3. Surgical procedures before admission (chronic chiefly).
4. Local and general treatment previous to admission (acute), with the dates and results of each (chronic).
5. Aerobic and anaerobic bacterial cultures of the blood (acute) and the lesion (acute and chronic).

6. Complete blood count (acute) as well as blood volume and blood chemistry (chronic).
7. Temperature studies (acute and chronic).
8. Primary and secondary local and systemic drug treatment (acute and chronic).
9. Primary surgical treatment (if any) and its relationship to the onset of infection and the beginning of drug therapy (acute and chronic).
10. Quantitative and qualitative bacterial studies of blood (acute) and lesion (acute and chronic) twice a week.

RECORDING RESULTS

In estimating the results of drug therapy in surgical cases it is obvious that we cannot use such simple terms as "recovered" or "died," because there may be clear evidence of benefit from the drug and yet death from the operation or from the disease itself. In some cases death may ensue before there is certainty with regard to benefit from the drug. The appraisal must be made from the point of view of the effect of the drug on the infectious process.

In some cases the result is immediate and surprising—one might almost apply the term "brilliant" or "excellent." In other cases the benefit is definite and reasonably certain but not particularly startling. This might be designated as "good." In many cases the benefit is decidedly questionable. One cannot say that the patient could not have done just as well without the drug; other factors seemed to be more important, the time of recovery was not materially shortened, and so on. The result here must be designated as "questionable." In still other cases it is quite evident that the infection progressed unchanged or went on to a fatal termination in spite of the drug. Here one can say with certainty that there was "no effect."

Any group of investigators working in different places on the same program should follow the same criteria as closely as possible for estimating the results. They should frequently present the data from their own cases to other investigators to check up on their own estimates. This can be done by frequent consultation between the leaders of the different groups.

One would wish to simplify this problem, but it is complicated and it is a mistake to be blind to the inherent difficulties. It is only by recognizing them that we can find a way to overcome them. And they can be overcome by wise planning and diligent effort.

SUMMARY

A. Surgical infections differ materially from medical infections in the following respects:

1. Necrosis of tissue or accumulated purulent exudate is present in surgical infections in contrast to the diffuse cellulitis of medical infections.
2. The dead tissue must be removed or evacuated or absorbed and replaced by scar tissue in surgical infections while inflamed tissue without necrosis returns to normal in medical infections.
3. There is frequently a mixture of organisms in surgical infections in contrast to a single species or virus in medical infections.
4. Necrotic tissue and thrombosed blood vessels prevent certain elements in the blood and medication from reaching the focus in surgical infections in contrast to patent and perhaps dilated blood vessels permitting the inflow of blood elements and medication into medical infections.

5. There is only local (if any) immunity in surgical infections in contrast to general immunity, which may hasten recovery, in many medical infections.

6. Necrotic tissue and pus in surgical infections may inactivate or inhibit certain medications which may be very effective in medical infections.

7. Incision usually benefits surgical infections, while it does positive harm to medical infections. Incision in surgical infections must be properly timed to do the least harm and the most good.

8. Surgical infections, being local, permit the local as well as the general use of drugs, while medical infections usually permit only their general employment. (Exceptions to this are such surface infections as erysipelas, tonsillitis or meningitis.)

B. For the foregoing reasons the evaluation of drug therapy in surgical infections is infinitely more difficult than in medical infections.

C. Drug administration in surgical infections may be prophylactic or therapeutic.

1. The prophylactic use of drugs is possible in war wounds, in contaminated accidental wounds of the soft parts, in compound fractures and burns in civilians and in operations on contaminated regions of the body, such as the alimentary canal.

2. In order to evaluate drugs properly in these cases there must be a comparison of drug treated cases with non-drug treated controls. These controls must alternate with treated cases without any selection of cases. This group presents a fixed starting point.

3. The appraisal of the therapeutic value of drugs in established surgical infections is much more difficult because there is no fixed starting point. The infection may have begun weeks, months or years before the drug treatment is started, during which time it may have had all kinds of treatment, any number of secondary contaminations, profound alterations in blood chemistry, in the nutritional status and in morale. It is difficult to run a parallel control series.

(a) In established infections the control may have to be the previous course of the case itself.

(b) However, if it can be shown that drug treatment obviates the necessity for surgery or makes possible a more conservative procedure or shortens the healing time or permits primary closure or early secondary closure which would not have been possible without the drug, its value may be demonstrated.

D. All these facts indicate the difficulty of evaluating drugs in the treatment of surgical infections. A carefully laid out plan should be followed and a number of different investigators in different cities should study the problem in a uniform manner, comparing and pooling their results.

E. Results of drug therapy in surgical infections may be designated by the terms (a) brilliant, (b) good, (c) questionable and (d) with no effect.

F. In the prophylactic studies, and in established infections when controls are used, the results in treated cases must be significantly better statistically than the controls before the benefit can be certainly attributed to drug treatment. When controls are not used the results must be repeatedly and consistently "brilliant" or "good" in a large series of cases before the benefit of drug treatment can be considered clearly proved.

THE GUILLOTINE AMPUTATION

MAJOR GENERAL NORMAN T. KIRK

SURGEON GENERAL, UNITED STATES ARMY

AND

LIEUTENANT COLONEL FRANCIS M. McKEEVER

MEDICAL CORPS, ARMY OF THE UNITED STATES

Drainage of infected or potentially infected tissues has always been a fundamentally sound surgical principle. Deviations from this basic principle, although occasionally resulting in a sensationally short period of convalescence, most often prolong recovery, endanger survival or result in death. The occasional success of a procedure which is a violation of sound principle does not justify the procedure in surgery any more than does the prosperity of one undetected criminal justify crime.

The guillotine or open amputation is an operation based on the sound surgical principle of drainage for infection. The efficacy of the guillotine amputation as a life saving measure and a "length preserving" operation was definitely established in the World War of 1914-1918. So lethal were the consequences of primary closure of battle wounds that it was necessary for the Surgeon General of the American Expeditionary Forces to issue an order prohibiting the closure by primary suture of any battle wound.

Experience to date in World War II indicates that the sulfonamide drugs have not altered the basic surgical principle of "drainage for infection." Closed amputations of extremities traumatized beyond repair is dangerous to life and wasteful of useful functional bone length even though the sulfonamides are used systemically and topically. This does not mean that these valuable drugs should be discarded. On the contrary, the sulfonamides should be employed routinely along

Colonel MacFarlane,¹ the consulting surgeon to the Canadian Overseas Force, in commenting on the results of chemotherapy in the African campaign of 1941 emphasized the necessity for drainage in traumatic wounds. He stated that despite the liberal use of the sulfonamides the battle casualties from this campaign

Fig. 2.—Appearance of (A) stump six weeks after guillotine amputation: bone ends clean, soft tissue healed over end of bone; (B) final result, three months after injury: a reamputation has been performed at site of election eight weeks after guillotine amputation.

invariably were severely infected when closure of wounds was carried out. He also stated that patients whose wounds were left open and permitted to drain and heal by granulation recovered more quickly and with fewer fatalities.

The same may be said of our own casualties returned to this country. In one group of 150 amputees, which included patients from all theaters of operation as well as the zone of the interior, the following facts were evident: 1. The systemic status of the patients whose amputated extremities had been left open was universally excellent. 2. The only patients showing the exhaustion of prolonged infection were those in whom the development of infection made imperative the opening of a previously sutured stump. 3. The guillotined extremities all presented a good granulating surface, which was easily and in a short time prepared for closure. 4. The only severely infected stumps were those in which closure was attempted and failed. Their preparation for ultimate closure took longer than the preparation of those extremities which had been left open to granulate. 5. In no instance was the closure of a properly managed guillotine stump complicated by severe infection, nor did it require lavish sacrifice of length.

The guillotine amputation is definitely indicated for any extremity which requires removal when infection is already established or in which the probabilities of contamination make the chances for primary healing questionable. Thus it is the operation of election for an extremity which must be removed because of a severe joint infection or an infected compound fracture or for a severely traumatized extremity in which amputation becomes necessary because of injury to the

Fig. 1.—Anteroposterior and lateral views of severely infected shotgun fracture of ankle, with gangrene of foot.

with sound surgery. Critical observation of penicillin indicates that more should not be expected from its use. If the basic principles of sound surgery are ignored, penicillin therapy cannot be expected to be effective.

This paper, in a symposium on "Amputations," is published under the auspices of the Section on Orthopedic Surgery.

circulation or soft tissues. The guillotine operation is also to be chosen when operating conditions are not adequate. The patient recovering from severe shock will tolerate a guillotine amputation, as it can be performed much more rapidly than a closed amputation and with less additional shock.

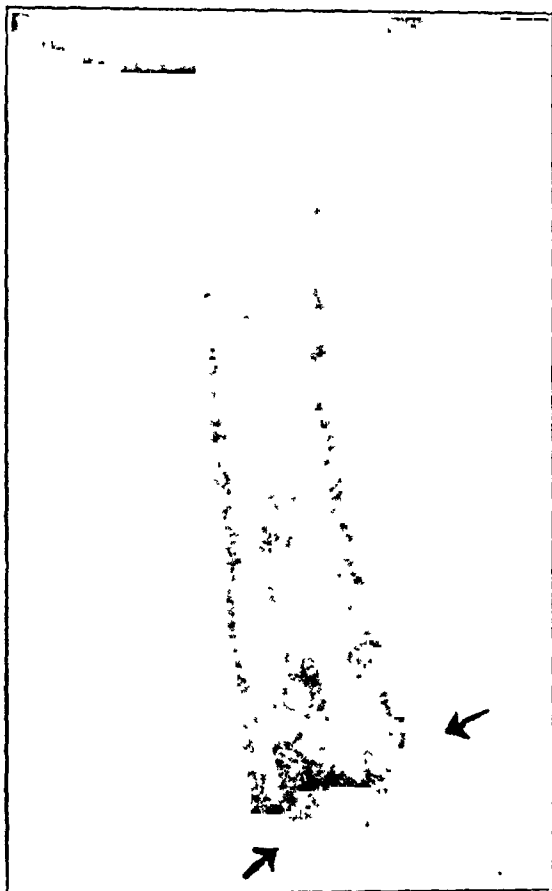

Fig. 3.—Guillotine stump four months after amputation, showing sequestrum and infected osteophytes due to improper handling of periosteum at operation

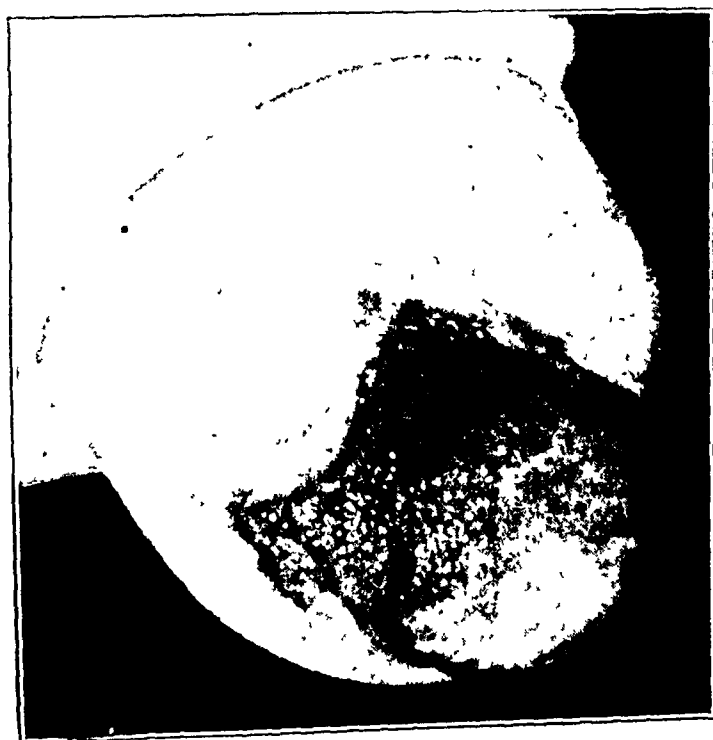

Fig. 4.—Thigh stump without traction four weeks after operation skin receded from bone end

The guillotine amputation is a two stage procedure. The first stage is the removal of the damaged portion of the extremity. After the open cross section resulting from this stage has healed by granulation and scar

contracture, the second stage consists in the operative procedure to produce the final stump for a prosthesis. This may be a simple plastic closure or it may be a reamputation at the site of election.

The technic of the first stage or of the actual removal of the undesirable portion of the extremity is aimed at producing a slightly concave open cross section of the extremity, with the skin slightly longer than the superficial muscle, the deep muscle slightly shorter than its overlying muscle. A circular incision is made through the skin at the lowest level compatible with viable tissue, and the skin is allowed to retract; the fascia is then incised in a circular manner at the level to which the skin has retracted. The superficial layer of muscle is then cut at the end of the fascia and permitted to retract. At its point of retraction the deep layers of muscle are cut through to the bone. After the deep muscles have retracted, the periosteum of the bone is cleanly incised and the bone sawed through flush with the muscles

Fig. 5.—Below knee stump two months after operation, no traction used skin receding and bone protruding.

The bone end is not treated by the aperiosteal technic. No cuff of periosteum is removed as in a closed amputation. Bone denuded of periosteum will sequestrate in the presence of infection, and the removal of a cuff of periosteum will result in a ring sequestrum. Clean sharp incision of the periosteum is important. Bone left uncovered in the stump by elevated tags of periosteum due to rough handling will also sequestrate, and the shreds of periosteum in the muscle will cause infected osteophytes which delay healing.

Large vessels are transfixed and smaller vessels tied with plain catgut. The nerves are cut short and allowed to retract into fascial planes. The larger nerves are ligated with plain gut just proximal to the point of section to guard against bleeding from their artery. The entire cross section of the extremity is left open.

For a compound fracture or for an infected fracture, the site of amputation is at the site of fracture. The incision does not always have to be transverse to the long axis of the leg but may be altered to meet circumstances. If necessary to preserve length, the incision may be at a diagonal to the long axis of the leg or racket shaped. For example, to perform the guillotine amputation for an infected compound fracture just

above the ankle joint and an osteomyelitis extending through the entire shaft of the fibula with draining sinuses, a circular incision could be made just above the ankle and extended longitudinally up the lateral side of the leg to permit removal of the entire fibula and drainage of the infected tissue. This would save a below the knee stump with a functioning knee joint. Any attempt to perform a closed amputation in these circumstances would demand a midhigh amputation with greatly increased disability.

For no surgical procedure is the proper postoperative care more important than for the first stage of the guillotine amputation. Skin traction is absolutely essential after the operation. It must be applied immediately and kept up continuously. This in no way interferes with dressing the infected wound. The traction can be released for dressings. When traction is applied immediately after operation the potentialities of the concave

gins and when bacteriologic studies show a low bacterial count, particularly of streptococci, the tissues will tolerate a surgical closure. These conditions can usually be brought about by careful postoperative care in six to eight weeks following the first operation. Prior to performing the operation for closure, roentgenograms of

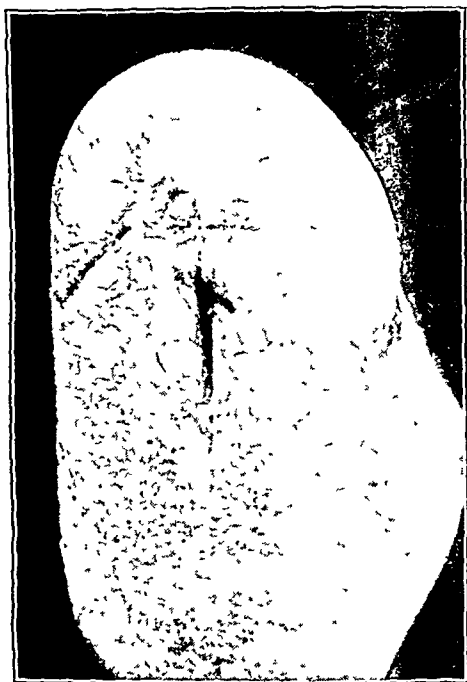

Fig. 6.—High stump six weeks after operation. Skin traction continuously since guillotine amputation. Skin healed by scar. Bone covered. Ready for simple plastic closure.

cross section of the extremity are fully developed. The skin, owing to its elasticity, is gradually pulled down over the muscles, the end of the bone becomes covered by granulation tissue and the skin margin closed by scar contracture.

If skin traction is not continuously applied, the concave cross section of the leg becomes a greatly exaggerated convex cross section, with an inch or two of uncovered bone protruding and a large collar of granulation tissue intervening between the constantly receding skin margin and the bare bone. Such a neglected stump requires a reamputation at a higher site, with unvaried sacrifice of ultimate length.

The second phase in preparing the open amputation for use of a prosthesis consists in an operative procedure to cover the end of the bone with healthy pliable skin, which has good circulation and normal sensation. This closure is usually a simple matter. When there is an area of clean granulation tissue covering the bone end, when there is no redness or edema of the skin mat-

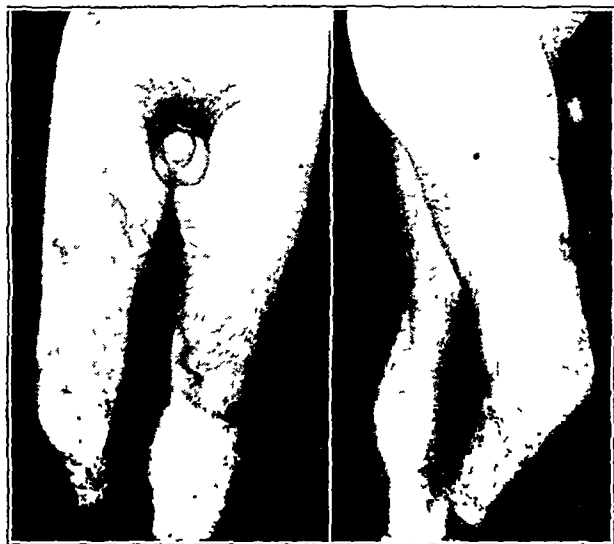

Fig. 7.—Below knee stump eighteen months after pedicle skin graft. Ulcer throughout graft. Patient has never been able to use prosthesis.

the bone end should be obtained to determine whether sequestration of bone is occurring. If a sequestrum is forming, closure should be delayed and the sequestrum removed at the proper time.

Closure is usually a simple procedure. The scar is excised *en bloc* to good skin, the skin undermined to mobilize it and sutured over the end of the bone. If the scar is so firmly attached to the bone that cutting it loose would leave a projecting piece of bone under the

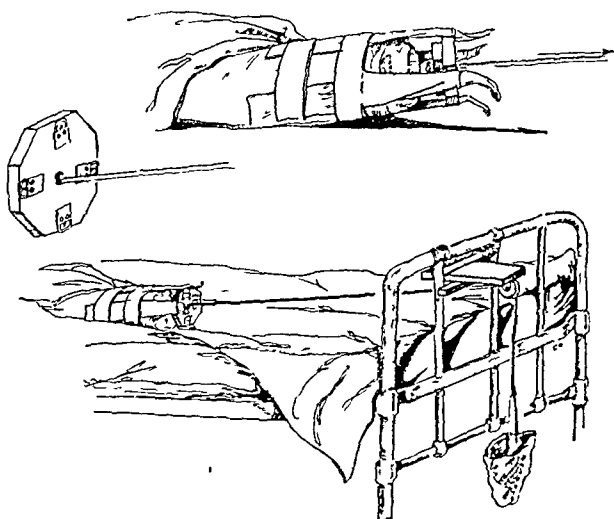

Fig. 8.—Diagram of method of applying traction to open stump (from "Amputations," by N. T. Kirk).

closed skin, a thin section of bone may be removed *en masse* with the scar, by sawing a piece $\frac{1}{8}$ to $\frac{1}{4}$ inch in length from the end of the bone. It is not necessary to free the muscles and fascia from the bone and resuture them over the end. They are already firmly attached and will carry out their function well. The

great longitudinal elasticity of the skin makes possible a definite gain in length of the flaps. Occasionally a plastic section of the skin has to be done after mobilizing it thoroughly to cover the stump end. This can be done without danger of losing skin if the mobilized flap is given a broad enough base for blood supply. Skin traction may also be used advantageously after the plastic closure and be employed until healing results if there is any evidence of tension. This technic enables closure to be effected without additional sacrifice of length when there is no abundance of stump.

Skin grafts, even of the pedicle type, are of little value in effecting closure of the open amputation stump. Because of the avascularity of the stump end, the pedicle is usually lost. If successfully attached, the imperfect sensation and small vascular margin of safety of the flap will not tolerate the trauma of wearing a prosthesis. The pedicle blisters and ulcerates under the pressure of the artificial limb bucket. Repeated invalidism and ultimate reamputation at the request of the amputee is the final outcome. Rarely a pedicle graft may be necessary to save enough of the forearm stump and avoid sacrificing the elbow. The wear and tear of an arm prosthesis is much less than that of a weight bearing artificial limb. Occasionally a split skin graft may be

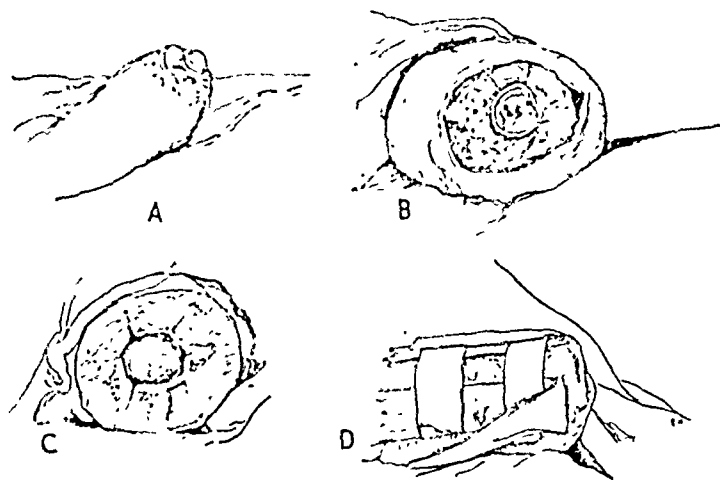

Fig. 2.—Results of traction: A, B, stump on admission; C, sixteen days with traction; D, traction straps turned back; skin approaching end of bone (from "Amputations," by N. T. Kirk).

used to cover a large granulating surface in order to accelerate healing prior to ultimate closure. This should not be necessary if traction is properly used in the post-operative period.

If there is an abundance of stump, a reamputation at the site of optimum function with primary closure can be carried out without danger of realighting infection. For example, if the stump is above the ankle the reamputation can be carried out at the site of election in the middle third of the leg, or if a portion of the foot remains a Symes amputation can be performed and closed by primary suture.

The sulfonamides have a definite place in secondary closures and should be used both systemically and locally. Since there is no sloughing muscle or open fascial planes when the secondary closure is carried out, they have less unfavorable factors to overcome and are more effective. Their use permits earlier closure under these circumstances than was possible prior to their advent.

SUMMARY

1. Closed amputations are dangerous to life and wasteful of stump length in the presence of established infection or potentially infected extremities.

2. The local and systemic use of sulfonamide drugs has not obviated the dangers from closed amputations in the presence of infections.

3. The open or guillotine amputation is definitely indicated if the possibility of infection is present. Its use in the presence of infection will save life and also useful stump length.

4. The proper after-care of the guillotine amputation is an essential for good results. Continuous skin traction from the time of amputation is imperative if good results are to be obtained. Otherwise, reamputations with resultant loss of bone length will occur.

PAIN AFTER AMPUTATION AND ITS TREATMENT

COMMANDER JAMES C. WHITE (MC), U.S.N.R.

In this discussion of intractable pain which may follow amputation I should like to begin by pointing out how little is known about it, and what an opportunity is awaiting surgeons in the military forces today for gaining a better insight into its mechanism, as well as for devising effective methods of treatment. With the promising start made by Mitchell, Morehouse and Keen¹ in the investigation of painful nerve injuries during the Civil War, it is surprising how little progress was made by our immediate predecessors from 1914 to 1918. Perhaps this was due to the fact that the best neurosurgical minds, like the late Dr. Cushing's, were taken up with the problems of cerebral trauma, and that therefore lesions of peripheral nerves, which cause intense pain, were neglected. With the present broadening of neurosurgical interest to include the sympathetic nervous system and the problems of intractable pain, we should do better. Painful amputation stumps are likely to be the most common of these distressing conditions and are certain to be a major reconstruction problem for years to come.

MECHANISM OF PAIN

Neuromas.—Microscopic examination of an end bulb neuroma shows it to be a branching mass of Schwann cells and proliferating axones embedded in scar tissue. This would seem to be an ideal setup for the production of pain, and it is remarkable that the great majority of neuromas are not painful. Trotter,² in his classic essay on "The Insulation of the Nervous System," pointed out that "the general tendency of all forms of sensation yielded by a regenerating nerve to develop a certain resemblance to pain reminds us that regenerating fibers resemble pain fibers in a lack of insulation. It is probable, therefore, that imperfect insulation tends to render all fibers less sensitive than normal,

This paper, in a symposium on "Amputations," is published under the auspices of the Section on Orthopedic Surgery.

2. Trotter, Wilfred: *The Collected Papers of*, London, Oxford University Press, 1941.

but more apt when effectually stimulated to respond in an exaggerated explosive way." In a neuroma the naked nerve endings are totally devoid of any insulating myelin. Furthermore, scar tissue in an amputation stump in which these end bulbs are embedded contracts and also reduces the supply of circulating blood. This is particularly true when there has been infection and delayed healing. In recent experiments Lorente de No³ has shown that a nerve made anoxic fires off repetitive stimuli, which suggests that impaired circulation in a neuroma may be a source of painful impulses.

Why most neuromas should be painless and others the cause of long lasting torture is quite unknown. This cannot be explained entirely on the basis of any idiosyncrasy on the part of the individual patient (such as a low threshold for pain), because in certain individuals with multiple amputations only a single stump will become painful (Livingston⁴). Why is removing the pain-producing neuroma so seldom successful? A new neuroma will form, but sometimes the pain recurs sooner than its peculiar end bulb can be reproduced. This and the fact that more proximal crushing or chemical destruction by infiltrating the nerve trunk with alcohol fails to give relief has forced investigators to predicate a central extension of the pain mechanism. Mitchell, Morehouse and Keen¹ described an ascending neuritis, but numerous examinations of sections of nerves removed during therapeutic neurectomies have failed to show evidence of any histologic alteration. It is therefore far more likely that the central disturbance is due to reflex changes in the spinal or cortical levels, as has been suggested by Livingston⁴ and Riddoch.⁵

The Phenomenon of the Phantom Limb.—After amputation most persons are conscious of their absent member. This may be for only a brief period after amputation, and the sensation may not be painful. Usually it disappears when the patient first starts to use his artificial limb. On the other hand, the sensations may become acute torture, so that the victim complains that his fingers are being compressed into the palm of his hand, or that his toes feel as though they were being constricted in a vise. He may even state that a specific pain from which he suffered before amputation persists unchanged in the missing part. Riddoch comments on the fact that "the prevailing posture of the phantom is that of the part at the time of amputation. It is as if the postural model had become frozen when normal stimulation ceased." These sensations are always located in the periphery of the limb, especially in the fingers or toes, where there is the greatest concentration of sensory nerve endings. The missing hand or foot is sometimes felt in its normal position, but at other times it may shift centrally, so that in the case of a total arm amputation the phantom hand may be felt at the elbow or disappear into the shoulder stump. These are the reasons why the phantom phenomenon has been regarded as psychogenic and the patient regarded with suspicion as a psychoneurotic. As Leriche⁶ and Livingston¹ have stated, such a diagnosis is frequently incorrect and may therefore prevent adequate therapy.

Probably the primary cause of the phantom sensation is irritation within a neuroma of centrally conducting axones which formerly supplied the missing part. But this does not necessarily continue to be the case, in view of the other peculiar characteristics of the phenomenon mentioned and the fact that these may persist after all the known afferent connections have been severed. Riddoch⁵ has given a most convincing argument for believing that the phantom sensation is a projection arising from the postcentral sensory association areas in the cerebral cortex. According to him:

Stimulation by the processes of healing of the proximal ends of the divided nerves evokes sensations which are projected and interpreted as if the limb were still present. As has been said, they are never quite normal. These paraesthesiae, through simultaneous excitation of the schema underlying tactile localization and shape, are projected and animate the surface or outline model of the absent part. Similarly, irritation of fibers concerned with postural sensibility give rise to impulses which help to keep alive the postural model, so that the phantom is correctly placed and moves with the stump. These sensations, in the absence of pain, are, however, weak, so that, as a rule, only the peripheral segments, the hand or foot, which are most richly endowed with sensory end-organs and fibers, are represented in the phantom. Retention of the phantom is in part due to the abnormal qualities of the tactile and other sensations, in spite of their relative weakness and the antagonistic evidence from visual and other senses. During the stabilizing process of healing of the divided nerves, sensory impulses diminish, and sensations become correspondingly fainter, with the dual result that the phantom is increasingly less obvious in outline and projection of it is defective. In consequence, it gradually approaches the stump, into which it finally disappears and fades away. A new shape of the body is now accepted. In other words, there is no longer a conflict in evidence from the patient's senses. If, however, the phantom is painful, which is usually the result of grossly abnormal conditions in the stump, the phantom may persist indefinitely and retain its original position. Further, the hand and fingers are not only much more obtrusive and clearly defined, but more of the amputated part is represented by it. Voluntary movement is restricted or impossible because of aggravation of pain. When, however, pain in the phantom is successfully abolished by lateral chordotomy or early removal of abnormalities in the stump, the phantom may behave as if it had been painless from the first.

If this concept is correct, the development of a central projection would be expected to take time to become established in the sensory cortex, a point which has been mentioned by Riddoch and recently emphasized by Air Commodore C. P. Symonds.⁷

General Considerations.—Hilton⁸ considered pain in the nature of a protective mechanism, but in the amputation stump neuralgias it becomes a destructive mechanism, dangerous to the patient's morale. When pain of this type is allowed to become chronic, the cerebral cortex may become involved in its projection (Riddoch), and in addition the patient usually develops an addiction for morphine. These complications force us to define the ideal time for surgical intervention. Occasionally the pain subsides spontaneously, but more often than not it continues to get worse. I have recently operated on a patient suffering from a phantom foot of eighteen years' duration. A waiting period of over six months in any but the most stable individuals is dangerous because the psychic changes may become irreparable. We are therefore forced to formulate a rational plan of treatment for these patients.

With this purpose in mind I should like to begin at the point where all conservative orthopedic, physical therapeutic and neuropsychiatric procedures have been thoroughly tried and have failed.

SURGICAL TREATMENT

In undertaking this type of surgery, principle No. 1 should be to guard these patients against useless and mutilating operations. While working in France in 1927 I remember seeing a French veteran whose case illustrates many of the difficulties in the treatment of post-traumatic pain. A penetrating wound of the hand had led to chronic suppuration, fibrosis and pain. In the intervening ten years he had undergone a long series of operations including amputation above the wrist, resection of painful neuromas and subsequently progressive amputations up the arm which ended with a painful shoulder stump. Periarterial sympathectomy of the subclavian artery and section of the posterior roots of the brachial plexus failed to put an end to his suffering, which was finally terminated through suicide by hanging. At that time little was known about what to do and, equally important, what not to do about a case of this sort, as this tragic story shows. We are learning slowly, and many points are illustrated by this story. In the first place, it is vitally important not to undertake any ineffective procedures. Col. F. M. McKeever⁹ has observed that the pain in an amputation stump is usually increased by any operative procedure, even by revision of flaps, where the severed stumps of the major nerves are not even exposed. It is therefore of vital importance to recognize that certain procedures are useless and should never be employed. At a meeting of military neurosurgeons convened by Lieut. Col. R. G. Spurling at the Walter Reed General Hospital in September of last year it was agreed that the list of nonbeneficial and actually harmful procedures should include the following:

1. *Repeated resections of neuromas.*
2. *Neurectomies or interruption of nerve trunks at higher levels.* Livingston¹ has recorded a resection of the brachial plexus in a painful upper arm stump without benefit, and numerous other case reports from the time of Mitchell, Morehouse and Keen¹ are on record which attest its futility. Another variation of this procedure is the transection of a painful nerve trunk with immediate suture to prevent neuroma formation. Leriche⁶ describes its use, but without striking results.

3. *Reamputation for the relief of pain.* Reamputation, as emphasized by Leriche⁶ and Riddoch,⁵ must never be considered, as the pain nearly always recurs in the new stump and usually is made a great deal worse. There is only one exception to this rule: When the stump is badly constructed and a liability on mechanical grounds, a reconstruction may be in order. Such a revision must be done at an early date, however, if it is to have any chance of relieving pain.

4. *Periarterial sympathectomy.* Successful results in minor forms of amputation stump pain by this operation have been recorded by Leriche⁶ and Homans.¹⁰ Leriche, however, states that it should not be considered when the neuralgia is severe. It is my personal feeling that the procedure is nonspecific and that its

effects are due to the transitory rise in peripheral circulation that results from the increased elimination of heat following any injury to the tissues. Similar effects can be produced more simply by procaine block of the vasoconstrictor nerves or by fever therapy. In this connection it is of particular interest to record the observation made by Major F. H. Mayfield and Capt. J. W. Devine at the Percy Jones General Hospital that soldiers with malaria are relieved of pain from nerve injuries during bouts of fever.

5. *Intrathecal injection of alcohol.* This procedure, proposed by Dogliotti,¹¹ has been advocated for the relief of painful amputation stumps in the lower extremity. I have seen it work successfully only once out of seven trials. Furthermore, it carries as great a risk of paralyzing the bladder as section of the spinothalamic tract, or even greater. For any patient who has chronic pain and is even a fair surgical risk I should prefer to cut the pain tracts in the spinal cord.

6. *Posterior rhizotomy.* Sectioning the posterior roots of the brachial plexus is a dangerous and mutilating procedure. The widespread and complete anesthesia which results is both annoying and incapacitating to the patient, if he has a useful stump. For this reason, and even more because the anesthetic stump usually continues to be painful, this procedure should never be undertaken. I have seen a man with a painful amputation stump at the shoulder continue to suffer after division of all the posterior spinal roots from the third cervical down through the third thoracic. Riddoch⁵ also emphasizes the futility of posterior rhizotomy in these cases and states that he has seen the pain continue after the anterior as well as posterior roots of the brachial plexus have been cut.

Procedures which may be successful include the following:

1. *Single resection of a painful neuroma.* Leriche⁶ and also Bailey and Moersch¹² claim that this operation never produces lasting results, as the neuroma invariably recurs. Riddoch,⁵ however, in his article on amputation stump pain is less pessimistic. My personal experience leads me to concur with Riddoch that the removal of a palpable painful neuroma is worth a single trial, provided the pain disappears when the neuroma is infiltrated with procaine. It is a minor procedure and is occasionally successful, particularly if performed very early, before the development of a local functional disturbance in the sensory cortex. In excising the neuroma it is well to use the technic suggested by Boldrey¹³ and adopted by Lieutenant Colonel Spurling at the Walter Reed General Hospital of burying the end of the nerve in a drill hole made through a neighboring bone, so that the formation of a fresh neuroma will be prevented by the constricting action of newly formed periosteal bone. Both Spurling and I have used this procedure a number of times in the treatment of neuromas from penetrating war wounds, and the results to date have been promising.

2. *Sympathectomy.* When local measures are unsuccessful, the possibilities of treatment by chemical blocking of the sympathetic fibers to the extremity or by

ganglionectomy should always be considered. These are the only minor and nonmutilating procedures that offer any likely chance of success. It should be emphasized that there is no convincing evidence that the peripheral sympathetic axones carry any sensory impulses or that somatic sensory fibers run in these trunks to the peripheral blood vessels. Nevertheless, sympathetic block has resulted in a large number of dramatic cures, both of local stump and also of phantom limb pain. It has been my impression that sympathetic paralysis is most likely to benefit patients whose pain is felt in the distal end of an extremity, and particularly when that extremity is habitually cold, cyanotic and clammy. Individuals with chronic vasospasm usually have an emotionally labile disposition and seem to develop unusual complaints after injury, which can

the injection should be repeated. Leriche and Homans in particular have found that in the course of a series of injections the pain may be relieved for increasing intervals, until finally it does not recur. If the improvement is only temporary, repeated blocks are not likely to be helpful; but the chances of lasting relief following permanent vasodilatation by ganglionectomy are great.¹⁶ On the other hand, when diagnostic injection of procaine produces clearcut vasodilatation and anhidrosis but does not influence the pain, treatment by sympathectomy need be given no further consideration.

When this relatively innocuous type of surgery cannot be used, the attack must be shifted to the central nervous system. Before recourse to more radical intervention on the spinal cord or brain, all aspects of the problem should be reviewed with a competent neurolo-

Case	Condition	Level of Analgesia	Relief
4 William D.	Gritti-Stokes amputation for thromboangitis obliterans, then complained of deep aching pain in stump, 3½ years' duration	9th thoracic segment	To death, 5½ years later; this patient subsequently developed pain in stump of other leg after a second Gritti-Stokes amputation and painful gangrene of fingers; died after cervical chordotomy on opposite side
5 Nellie T.	Burning pain in stump since thigh amputation for osteomyelitis 8 years before; at other hospitals had had unsuccessful sciatic neurectomy, multiple excisions of neuromas and intrathecal alcohol injection, latter caused bladder disturbances for 1 year	8th thoracic segment	Complete relief at 3 months
6 Luana H.	Midthigh amputation following septic abortion; local pain in stump of 2 years' duration; previous intrathecal alcohol injections had paralyzed bladder without mitigating the pain	10th thoracic segment	Complete relief for over 5 years but has complained of radicular pain at level of laminectomy

often be corrected by restoring a normal circulation. The most valuable reports on this method of treating pain in amputation stumps and causalgia have been published by Leriche,⁶ Livingston,⁴ Homans¹⁰ and de Takáts.¹¹ Two other successful cases of relief of intractable pain after traumatic amputation and also a review of the technic of ganglionic injection and resection have been described by White and Smithwick.¹ Cases treated at the Massachusetts General Hospital by injection of procaine and by sympathectomy are summarized in table 1. It is always best to begin with a diagnostic blocking of the paravertebral ganglions with procaine. This is a simple test, and occasionally a single injection will give enduring results. When freedom from pain lasts a number of hours or days,

gist and a neuropsychiatrist. It must be constantly borne in mind that any ineffectual and mutilating procedure, by adding another psychic trauma, will inevitably increase the patient's suffering and loss of morale.

3. *Section of spinothalamic tract (chordotomy).* Cutting the anterolateral pathway by which the sensation of pain ascends within the spinal cord is in general far more effective than section of posterior spinal roots. Furthermore, it is not followed by numbness or loss of position sense, as all components of sensation except appreciation of pain and temperature are spared. From my personal experience I feel certain that tenderness and burning pain which are localized in the stump itself can be relieved by chordotomy. Three typical cases treated in this fashion are summarized in table 2.

14 Scupham, G. W.; de Takáts, Géza; Van Dellen, T. R., and Jesser, I. H.: *Vascular Diseases*. Seventh Annual Review, Arch. Int. Med. 68: 599-660 (Sept.) 1941.

16 In good risk surgical cases operative resection is always to be preferred to attempts at destruction of these structures by paravertebral injection of alcohol. Even in the most expert hands chemical block is not always effective, and complications are more frequent than in resection under direct vision.

In the case of severe pain and other peculiar sensations from a phantom limb, the decision as to whether relief can be obtained by spinothalamic tractotomy becomes most difficult. In the extensive experience of Bailey and Moersch¹² at the Mayo Clinic this operation has failed consistently. Riddoch,⁵ however, does not believe that this is necessarily the case; but when pain has been present for a protracted period so that it has been stamped indelibly on the cerebral cortex, no spinal interruption can be counted on to free the patient from the consciousness of his phantom. In the Neurosurgical Service at the Massachusetts General Hospital 3 patients complaining of pain referred to the missing leg have been submitted to spinothalamic tractotomy (table 3). It will be seen that the severe crushing or pinching pains in the phantom foot have been relieved in each instance. In the first patient, whose phantom sensations had been present for eighteen years, it is remarkable that relief from pain should have been so complete. He writes: "No sensation to speak of in the missing leg, but some throbbing at times in the little toe and ankle bone. No movement of the foot or toes. The operation has also eliminated the spasmodic jumping of the stump to almost 100 per cent." The second patient has had a sense of stiffness in his

tion occurs in the parts which have the greatest concentration of sensory nerve endings and therefore the greatest representation in the cerebral cortex. The cortical area for the hand is many times greater than the corresponding area for the foot.

In our present state of limited knowledge it is wisest to accept the fact that even a perfectly executed chordotomy, which is known to interrupt all forms of peripheral pain, can be counted on to give relief only when the disagreeable sensations are clearly confined to the amputated stump. Surgical intervention could be undertaken much more freely if objective tests could be devised for differentiating peripheral from central pain. It is possible that pain originating in an amputation stump can be identified by diagnostic blocking of its nerves with procaine. To date this method has not been explored, but if a sufferer from pain in a phantom leg should continue to complain after spinal anesthesia, or a phantom arm should still be present after an effective block of the brachial plexus, then it would seem most likely that the sensation is projected from the cerebral cortex.²¹

4. *Resection of sensory cortex.* In certain sufferers from major amputation stump neuralgia we shall be

TABLE 3.—*Relief of Phantom Limb Pain After Amputation by Section of Spinothalamic Tracts*

Case	Condition	Level of Anesthesia	Relief
7. Charles W.	Pain in phantom foot for 18 years following thigh amputation; 2 previous unsuccessful resections of neuromas	Not recorded	At 2½ years patient remains comfortable, although at times there is slight throbbing sensation in phantom little toe; spasmodic jumping of stump has ceased
8. Arthur N.	Crushing pain in phantom ankle following hip disarticulation for sarcoma 2 months previously	7th thoracic segment	In good condition and free from pain at 27 months, but has had awareness of phantom with some sense of stiffness in foot and big toe
9. Homer A.	Pinching, burning pain in phantom foot 7 months after hip disarticulation	9th thoracic segment	Complete loss of phantom sensations 8 months after chordotomy; still complains of spasmodic jerking of stump with sense of muscle cramp and of mild radiculitis at level of laminectomy incision

phantom ankle and big toe, but no pain. The third states that he has lost all sense of his phantom, but that when the muscles of his stump contract he is still aware of the cramplike contractions. This is not a sufficiently large series from which to draw definite conclusions, but it does prove that chordotomy can help in certain cases.

So far I have had no opportunity to attempt a high section of the spinothalamic tract for phantom pain in the arm and have been unable to find any successful report of its accomplishment. Yet chordotomy in the upper cervical segments or a tractotomy at the medullary (Schwartz and O'Leary;¹⁷ White¹⁸) or mesencephalic (Dogliotti;¹⁹ Walker²⁰) levels of the brain stem should interrupt the ascending painful impulses from the upper extremity. However, if the pain is a psychic projection from the cortex, no benefit can ensue. On theoretical grounds this mechanism is more likely to be present after amputations of the arm than the leg. It has been pointed out that phantom sensa-

forced to decide whether, in the presence of phantom sensations with evidence of psychic projection of the painful manifestations, we are justified in taking Riddoch's⁵ and Leriche's⁶ still earlier suggestion and extirpating the postcentral convolution of the cerebral cortex. Riddoch believes that the phenomena of the phantom limb, such as the persistence in the phantom of pain and postural sensations which antedate the amputation, can be explained only on the basis of cortical representation. He has stated that "destruction of the cortical sensory receptive mechanism in the parietal lobe, which is concerned with the development of postural and surface models and with recognition of change, causes immediate abolition of the phantom limb." This theory is corroborated by the case reported by Head and Holmes,²² in which disappearance of a postamputation phantom foot followed a lesion of the opposite parietal cortex. Mahoney²³ has recently put this theory to the test and carried out resection of the postcentral sensory cortex in a patient with a very disagreeable phantom arm. After two years the result remains a striking success. With lesions which involve

21. In a case reported by Michelsen²⁰ a depressed parietal fracture with cortical irritation of the postcentral arm area caused pain very similar to that experienced from a disagreeable phantom to radiate down the opposite arm. By infiltrating the brachial plexus I was able to obtain a complete motor and sensory paralysis, yet the pain which seemed to originate in her arm remained unaltered.

23. de Gutiérrez-Mahoney, W.: Personal communication to the author.

the corticothalamic connections, as pointed out by Gerstmann²⁴ and Nielsen,²⁵ the patient may lose awareness that he possesses portions of the opposite side of his body. This is the antithesis of the phenomenon of the phantom limb and gives additional backing for the surgical ablation of the postcentral convolution of the cerebral cortex. Further evidence in favor of the central representation of long-standing cases of phantom limbs and causalgia is seen in the pain which may be projected to the extremities in patients with tumors or injuries which involve the postcentral sensory areas in the cerebral cortex. Michelsen²⁶ has reported 5 instances which we have observed in the Neurosurgical Clinic of the Massachusetts General Hospital.

It is obvious that this projected attack on the highest station for sensation in the cortex is too new to permit any definite conclusions to be drawn. But the theory can be tested by turning down a small parietal bone flap under local anesthesia, identifying the motor strip by electrical stimulation and infiltrating the first post-central convolution with procaine.

5. *Release from states of agitation by frontal lobotomy.* A final possible approach to the problem of the unbearable phantom is the elimination of the sufferer's introspection and self-centered concentration on his condition which is the natural outcome of long-standing intractable pain. Ordinary psychotherapeutic methods alone have not been effective, but on theoretical grounds bilateral frontal lobotomy might accomplish this result, as it has benefited so many of Freeman and Watts's²⁷ patients suffering from agitated states. A successful operation of this type has been performed by Van Wagenen.²⁸ This patient had had a series of forty-five operations for chronic osteomyelitis, ending up with an amputation of the leg through the pelvis. He continued to have intractable pain in his phantom limb and was a confirmed morphine addict. In the year that has elapsed since the lobotomy he has recovered from his drug addiction, is able to look after his house and has only rare phantom sensations in his amputated leg, which are no longer a cause for serious concern. Another such operation has recently been performed by Dr. W. J. Mixter at the Massachusetts General Hospital, not for relief of pain, but in a young woman with an agitated depression secondary to a severe rhythmic tremor, probably on a postencephalitic basis. This patient had been studied in the Psychiatric Service by Drs. Stanley Cobb and M. E. Cohen but was referred to the Neurosurgical Service after failure of psychotherapy and two suicidal attempts. The tremor is, of course, still present, but her attitude toward it has changed profoundly, so that she no longer regards it as an insurmountable handicap in facing her friends or working in a war plant.

In conclusion, I wish to restate the fact that the attack on intolerable phantom sensations by resection of sensory cortex or by interruption of the frontal association fibers must be regarded as purely experi-

mental procedures which will require extensive investigation before their therapeutic value can be estimated. At present neither of these operations is to be considered except under pressure of extreme suffering and in a patient who threatens, unless relieved, to deteriorate into hopeless invalidism. If successful, they will open up a new method of surgical intervention for heretofore hopeless situations—conditions which cause so much pain and incapacity that the patients either become neurotic invalids and drug addicts or suicides. Every war has produced a new crop, and it may be possible to learn how to relieve the majority of them before the present conflict is over.

SUMMARY AND CONCLUSIONS

1. Incapacitating pain after amputation may be due either to irritation of end-bulb neuromas in the stump or, in the case of a phantom limb with persistence of pain and postural sensations, to their projection from the sensory areas of the cerebral cortex.

2. Local pain, burning and tenderness which are confined to the actual stump can be relieved by:

(a) Chemical or surgical interruption of the regional sympathetic outflow. These relatively minor and non-mutilating procedures are effective in an encouraging proportion of cases, especially when vasoconstriction and sweating are present to an abnormal degree.

(b) Section of the spinothalamic tract (chordotomy).

3. The peculiar pain and unpleasant postural sensations of the phantom limb will occasionally respond to sympathectomy or chordotomy, especially if the operation is performed at an early date, but these procedures invariably fail when the personality has started to deteriorate from prolonged suffering, introspection and morphine addiction.

4. In treating difficult problems of this sort it must always be borne in mind that any ineffectual and mutilating procedure, by adding another psychic trauma, must inevitably result in further suffering and loss of morale.

5. Experience has taught that a single resection of a neuroma is justifiable if it is definitely tender and the pain can be relieved by infiltration of procaine hydrochloride. Repeated excision of neuromas, neurectomy, reamputation at higher levels and resection of posterior spinal roots consistently fail and should never be used.

6. In the most severe forms of phantom limb pain, where in the past patients have sunk into hopeless invalidism, become morphine addicts or suicides, it may be possible to obtain relief by new types of surgical intervention directed at the highest centers in the brain. These comprise resection of the contralateral postcentral sensory convolution, from which the phantom sensations appear to be projected, or bilateral division of the frontal association fibers, which may be effective by freeing the patient of his intense introspection and anxiety. At present both must be regarded as purely experimental procedures, which will require extensive investigation before their therapeutic value can be estimated. The reason for presenting these procedures in their present theoretical stage is to call attention to their possibilities with the hope that they may aid in the solution of a hitherto insoluble problem.

THE AMPUTATION STUMP FROM THE PROSTHETIC POINT OF VIEW

MAJOR VERNON P. THOMPSON
MEDICAL CORPS, ARMY OF THE UNITED STATES

An amputation may be urgently necessary or elective. Once life has been saved, the usefulness of the stump becomes of paramount importance. These two functions of amputation are often quite inseparable, the good surgeon adapting the underlying principles according to the exigencies of the occasion.

SITES AND METHODS OF ELECTIVE AMPUTATIONS

There are desirable sites and methods of amputation which for a given partial loss of limb have a known usefulness and disability. A patient may reasonably require a stump of election to be a good one.

Selection of Site.—Sound elective amputations are those performed through a clean field at a site previously selected in the light of the traumatic, infectious and circulatory status of the limb which will permit fulfillment of all the basic requirements of a good stump. The age, sex and occupation and the social, economic and constitutional status of the patient, availability of a good limb maker and the surgeon's own experience are also important factors.

The Good Stump.—In the good stump there is freedom from pain, infection and circulatory disturbances. The soft tissues at the pressure areas are free from scarring. Nerve stumps are removed from pressure sites. There are no painful, projecting bone ends or spurs. The joints are freely and strongly movable by active muscles operating through an effective bony lever. In the lower extremity, end weight bearing and good knee joint function are of great value. Obviously, one cannot often have both.

Relation of Scar to Prosthetic and Anatomic Pressure Areas.—Since a stump's function is largely determined by the nutritional status of the pressure areas, the surgeon must know these areas for each type of stump and prosthesis. The best way to learn this is to examine various types of stumps of many years' usefulness. He will also observe that some features of a stump are more important than others. He will then be able better to evaluate various indications, sites, surgical techniques, postoperative methods of care and prostheses.

As the palmar aspect of the hand and fingers is primarily adapted to grasping, so is the plantar aspect of the foot and toes adapted to full weight bearing. Note that the pressure pads extend over the tips of the digits. Finger, toe, hand and foot stumps should imitate nature. Form them from long palmar and plantar flaps and avoid a sensitive stump end.

The anterior aspect of the knee and the ischial area are partially adapted to weight bearing. Under favorable conditions they will become adapted to full weight bearing.

The skin over the patellar tendon, tibial tubercle, anterior tibial condyle and head of the fibula will adapt itself to considerable weight bearing in a properly fitted

socket. The calf and thigh skin will take less pressure, but because of mechanical factors body weight is poorly transmitted through the lateral surfaces of the stump anyway.

Calf and lower thigh stump ends may occasionally bear some weight when the socket is fitted with an end pad. Therefore the scar should be posterior to the bone end. Even without end bearing, if the bone end is scantily covered transmission of the lateral pressure puts tension on the skin not well tolerated by scar adherent to the bone.

In the forearm and arm the stump end is not subject to pressure, since the prosthesis is actuated by lateral pressure. The scar should therefore be at the end of the stump.

Relation of Stump Shape to Prosthesis.—Major stumps of the extremities are somewhat conoidal throughout or terminate in a bulbous end. The Symes type stump at the heel and ankle and the end bearing knee stumps, the condylar, patelloplastic (Gritti-Stokes), capsuloplastic through the flare of the condyles will be bulbous, since they preserve a broad end bearing pad and are fitted with prostheses that are laced on, not fixed sockets entered from the end. Forearm, arm, lower leg and thigh stumps must be slightly conoidal in order to enter and withdraw from their fixed conoidal sockets. While these stumps must taper somewhat, they should not end in a projecting point of bone. Such a stump becomes painful and ulcerates on use. In the case of a midlower leg stump with a large muscular calf, the great bulk of the muscle bulges out in greater cross section than the tibial weight bearing area. The excess muscle should be cut off, since reasonable nicety in shaping the stump at operation will save much delay in conditioning and fitting it with a prosthesis.

The shape of the stump end is determined by the tissues utilized in covering it. The surgeon will bear in mind whether the stump is to be end weight bearing or not. If the first, then he must cover the end with skin and subcutaneous tissue capable of weight bearing. Avoid the useless practice of closing muscle flaps over the bone. It prolongs the period necessary to condition the stump to its final shape, size and consistency. Skin and the entire subcutaneous fascia will do very well. In certain stumps, muscular fascia or flat tendons are valuable in covering the bone end.

Efficiency of the Bony Lever as Regards Its Length and the Cross Section of Surrounding Soft Tissues.—The prosthetic efficiency of a bony lever is measured neither by its length nor by the size of the muscle cross section about it. If the bone is too long, as in amputation in the distal half of the lower leg, it is poorly clad with soft tissue. The slender, pointed stump end fits snugly in an unyielding socket; the skin is under constant pressure; its circulation suffers and stump troubles ensue. A shorter, suitably clad stump is better. Also the prosthesis can then be made to look like the other leg.

Conversely, with a midthigh or upper thigh stump, the usually large muscular cross section causes increased lurch from the telescoping of the limb within itself and the socket on weight bearing. While the bony lever is strongly actuated, its effectiveness is diminished by the play of the femoral stump within the soft tissues. In the thigh, every fraction of an inch above the lower thigh is precious.

While sites of election are still matters for discussion, it should be clear that there are a few basic physiologic and mechanical principles underlying the success or failure of each case. Intelligent application of these principles will increase the percentage of our successes.

SURGICAL TECHNIC

Most poor stumps are due to faulty surgery as to level, type and execution of procedure and postoperative care.

Tourniquet.—Too tightly applied tourniquets have caused serious vascular and nerve injury. If too loose, venous bleeding is increased. Familiarity with the location of the important vessels facilitates their isolation and clamping, so that a tourniquet is not strictly necessary. This should generally be the case in amputations for peripheral occlusive vascular disease. Otherwise the use of a tourniquet, preferably pneumatic, aids in a clean cut, accurate, gentle and reasonably rapid dissection.

Hemostasis.—The visible arteries and veins are ligated before release of the tourniquet. The larger arteries are carefully isolated with minimal soft tissue about them, doubly ligated at a gently clamped (not crushed) site with chromic O or equivalent, leaving a small distal tab. On large arteries, one of the ligatures should be of the transfixion type. On release of the tourniquet the bleeding points are grasped with fine forceps, avoiding unnecessary tissue, and ligated with plain OO or equivalent. The wound should be as dry as possible before closure.

Incision.—Before making the incision, visualize or mark the proposed levels of soft tissue and bone severance so as to have the proper ratio. It is better to trim off excess soft tissue at closure than shorten the bone to an unfavorable length.

The knife is carried at a right angle through the skin and superficial fascia to its deepest layer immediately overlying the muscular, paratendinous, capsular fascia or the periosteum, as the case may be. The physical and circulatory integrity of the skin and superficial fascial flap must not be impaired. It is much more easily reflected anyway in the fascial plane between it and the deep fascia. Where the deepest layer of superficial fascia is fused to the deep fascia, include this with the superficial flap; for example, the fascia lata of the thigh, the muscular fascia of the quadriceps femoris, the deep fascia, capsule, tendon or even bone (patella) in front of the knee; the thin layer of deep fascia over the subcutaneous surface of the tibia, in turn continuous with the muscular fascia of the anterior compartment and closely overlying the periosteum, which must be left behind.

Pattern of the Superficial Flaps.—All styles of flaps are derived from the circular method which cuts and devitalizes the least tissue and is therefore the surgeon's general choice in amputations of necessity. When the several layers, including the bone, are so cut at successively higher levels and left open, best with a bit of traction, many times a good, useful stump will result without reoperation or only a minor one. An oval flap may well save useful length. Short, long, equal, unequal, anterior, posterior or lateral flaps and longitudinal extensions should be used only when necessary and not to demonstrate some anatomy that need never see the light of day. The purposes of flaps are to cover the bone end with either weight bearing or

non-weight bearing soft tissue, to preserve the most useful stump length, to permit the necessary bone exposure with the least soft tissue trauma and to place the scar advantageously.

The Muscle Flap.—Closing muscle over the bone end merely delays stump conditioning while it degenerates and fibroses. Its bulk makes the end bulbous. Its slow shrinkage delays fitting the final prosthesis. Incise the muscular fascia distal to the bone level, incise muscle bellies circularly at the bone level, allowing the fibers to retract. The muscular fascia is closed over the bone. At sites where there is a broad muscular tendon, as the triceps of the arm and the calf group in the middle third, the muscle may be cleanly sliced off leaving a vascular tendinous flap sufficiently long to close over the bone, suturing it to the deep fascia anteriorly. In the distal forearm, the musculotendinous junctions are closed over the bone, in the proximal forearm only the muscular fascia.

The Periosteum.—The bone is exposed extraperiosteally for a short distance above the proposed saw line. A sharp knife is carried circularly through the periosteum $\frac{1}{8}$ inch above this line. The periosteum is sharply scraped distally, leaving no shreds behind. The bone is sawn off at a right angle to its long axis or in the lower extremity to the weight bearing line $\frac{1}{8}$ inch distal to the sharply cut, untraumatized periosteum. The marrow is not disturbed. For beveling the crest of the tibia, the periosteal incision is suitably shaped to allow beveling without further periosteal trauma. Sharp bone edges are smoothed with a sharp rasp. No proximal stripping is permitted, especial care being necessary at lines of muscular attachment, interosseous membranes and irregularly shaped bone, especially the fibula.

The Nerve Stump.—Nerves are identified during the formation of the flaps, clamped and cut. Before closure they are gently distracted and cut sharply across proximal to the level of the stump scar or level of pressure against the prosthesis. Larger nerves with vessels which would bleed are clamped and tied with small suture material.

Closure.—The flaps are tested for closure. Any excess is cut off. If there is too little soft tissue, more bone must be removed. Too much muscle is often the cause of undue tension of skin closure. The wound is closed in layers of muscular or deep fascia, and superficial fascia by interrupted mattress sutures of O catgut size or equivalent, as few as necessary being used and no more tissue being included than the suture strength calls for. The superficial fascia being approximated, moderately spaced fine silk skin sutures will readily coapt the skin. Drains are rarely necessary.

The Dressing.—A strip of xeroform gauze will add to the patient's comfort when the dressing is removed ten days later for removal of the stitches. A flat gauze layer is applied over the strip: then fluffed gauze is moderately snugged about the stump with a bandage, preferably elastic as bias cut muslin or stockinet.

Splinting.—Simple coaptation splints may be all that is necessary. Flexion deformities at the hip and knee are due to muscle spasm from the operative trauma, closure under tension increased by the swelling from roughly handled tissues. A light plaster splint is easy to apply and is efficient. Should there be unavoidable tension, traction through adhesive strips applied close to the wound is very helpful.

Postoperative Management.—Elevation of the part if the arterial supply is adequate will avoid much post-operative swelling. As the stump becomes comfortable and circulatory balance is obtained, periods of dependence increasing in duration and frequency are in order. Buerger-Allen passive vascular exercises may often be started before removal of the stitches. Barring fever, increased pain and drainage, the dressing is left undisturbed until this time. After the wound is healed, an elastic bandage is used to control circulatory stasis. Much of the "shrinkage" of the stump prior to wearing the prosthesis is merely recovery from the congested postoperative state. The better the surgery, the less the congestive and fibrotic condition to be recovered from. Graduated exposure of the stump to air, sun, soap and water, friction, exercise and dependence should condition the stump to permit fitting the prosthesis in weeks, not months.

Wearing the Prosthesis.—Early graduated weight bearing in a well fitting prosthesis is the final "making of the stump." It is not enough to start with a well fitted socket: it must be kept well fitting at all times. The stump pressure areas will not tolerate abuse or neglect. When localized discomfort and undue reactive rubor from spotty pressure appears, weight bearing must be discontinued and suitable adjustment made to the socket. Weight bearing only within tolerance limits is the rule. Particularly in the lower part of the leg, the inability of the tissue to stand the pressure exerted by the first socket on the weight bearing areas may soon become apparent again. Even if the skin does not break down, the daily period of weight bearing activity is diminished because of the feeling of weakness, insecurity, discomfort and pain. Early excessive pressure from poorly graduated use of a poorly fitted prosthesis produces permanent atrophic and fibrotic changes and diminishes the future usefulness of the stump. Poor skin hygiene is often followed by folliculitis and dermatitis.

Too often shrinkage is not promptly met by the use of interliners or new sockets. Frequently the second socket is made only after irreversible tissue changes have already taken place.

In various communities, limb makers are differently experienced in the fitting of the several types of stumps. The problem of the limb maker and his servicing of the prosthesis cannot be ignored. Some surgical and prosthetic customs are too fixed. Surgeons and prosthetists must learn from and cooperate with each other.

ELECTIVE SITES

Upper Extremity.—The function of the hand is determined by the ability to oppose the thumb and fingers and the security of its grasp. Any partial loss of the digits must leave a stump which will tolerate the friction and pressure of handling objects without discomfort. The patient should be able to tap hard on a table top with the end of the stump.

Distal Phalanx.—Very small tip defects will cover over well spontaneously, small ones with traction, and moderate defects require skin grafting. Larger defects usually require shortening of the bone to secure covering of the tip with pressure bearing palmar skin and subcutaneous tissue. Save the nail bed when possible. Save the distal interphalangeal joint but not at the expense of a sensitive stump.

Middle Phalanx.—Save all length possible. Since flexion is maintained by the sublimis, the deep flexor tendon need not be sutured.

Proximal Phalanx.—Its full bony length should be preserved. Suture the sublimis tendon to the dorsal aponeurosis, otherwise there will be no flexion control. A short stump is useless and should be removed if the other digits are intact. In the index finger, when strength of grasp is primary even a short stump usually adds to security. Ordinarily remove the short stump with the distal third to one half of the metacarpal by oblique osteotomy; dexterity and appearance are improved.

A stiff, straight finger is useless; remove it. But only one or two stiff fingers sufficiently flexed to permit opposition with a movable thumb are useful.

The opposing thumb is the most useful unit of the hand. Any part is useful even in complete loss of fingers, when artificial ones are used. An artificial thumb with movable fingers is less useful.

Principles.—Preserve all possible tissue initially. At definitive surgery, cover pressure areas with palmar tissue; leave a dorsal scar. Avoid closure under tension. Use a pressure dressing and elevation to avoid circulatory stasis. Don't use epinephrine in a finger block. Don't use a finger tourniquet.

The Forearm.—When no grasp whatever can be salvaged from a hand even with a prosthesis, maximum function will be obtained with a prosthesis fitted to the elective forearm stump. This is not higher than the middle and distal thirds or 2 to 4 inches above the distal ends of the radius and ulna. Some patients will insist on all possible length only to find the stump too long for a handy prosthesis and fit only for a paw. Use short, equal flaps for an end scar, since pressure in the prosthesis is lateral.

Above the middle and distal thirds, every fraction of an inch loses control and power until with a 2 inch stump the artificial hand is no longer operated effectively.

The Upper Arm.—Practically, an upper arm prosthesis is worn for esthetic purposes. Leaving the condyles as in an elbow disarticulation gives a clumsy stump and unnatural prosthesis. The elective site is 2 inches above the elbow joint line. With shoulder amputations, for the sake of appearance and simpler surgery, the humeral head is retained when the condition permits.

THE LOWER EXTREMITY

The loss of the toes causes little or no disability save for slight nondisabling loss of push off in vigorous walkers when the great toe is gone. A filler pad in the shoe adds to the patient's comfort. Place the scar dorsally and avoid disabling pain. Amputation through the base of the proximal phalanx is slightly easier and less traumatizing than disarticulation.

Metatarsals.—Preserve length only if the plantar flap will cover the bone ends and leave a dorsal scar. Carefully smooth the bone ends.

Metatarsal-Tarsal (Lisfranc) Amputation.—This fully end weight bearing elective site is very good when sufficient normal plantar flap is available to cover the end and give a dorsal scar. Preservation of the bases of the first and fifth metatarsals preserves better balance. A carefully fitted arch support and toe pad in the shoe

will improve function though the patient can walk without prosthesis or only a simple toe filler pad.

The Tarsal (Chopart) Amputation.—Amputation through the tarsus is not advised, since the muscle balance present in the Lisfranc is lacking. The next higher level is advised.

The Symes Amputation.—This amputation places the fully weight bearing pad of the heel over the distal ends of the tibia and fibula just above the level of the ankle joint. Since this stump is useless unless fully end bearing, the tissue of the heel pad must be normal before operation, be accurately placed on the lower leg at the operation, which must not impair the vitality of the flap, and be maintained in good position until firmly united. Reamputation at a higher level months or years later may usually be avoided by proper selection of cases, careful technic, reasonable use of the stump by the patient and fortunate absence of progressive vascular disease. The prosthesis is too clumsy to be satisfactory for most women but gives excellent weight bearing and a good push off on the ball of the artificial foot. The anterior scar should come just above the slight flare of the bones so as not to become irritated.

The incision consists of a transverse anterior portion and a vertical U passing under and in front of the heel from their common starting point at the malleolar level in the midaxial line of the leg as seen laterally. An anterior oval incision is somewhat simpler and easier to close. It is carried deeply through skin to ankle joint capsule, lateral ligaments, periosteum and plantar fascia. The ankle joint capsule is incised transversely, the astragalus freed from the mortice ligaments and displaced anteriorly, so as to permit dissection of the os calcis out of the posterior heel flap. This is carried out just extraperiosteally, great pains being taken not to traumatize the exposed soft tissue of the flap. Failure in these steps will jeopardize the vitality of the flap. Everywhere the deepest layer of the superficial fascia is left intact, in many areas the deep fascia as well and, of course, the achilles tendon. The muscles taking origin on the os calcis are left attached, though they may be dissected off the flap if originally included in it. The mortice is exposed by sharp extraperiosteal dissection and the malleoli sawed off one-fourth to one-half inch proximal to the tibial articular surface, the aperiosteal technic previously described being used.

After suitable ligation of the larger vessels the tourniquet is removed and as nearly perfect hemostasis as possible is obtained.

By this time the flap will have shrunk some, but the fitting of the long posterior flap to the anterior one takes judgment and patience. The bony stump must fit snugly in the center of the heel pad, which must not be permitted to slide sideways or forward. Ears may be judiciously trimmed but are usually better left alone. Small rubber drains in the corners and a snug pressure dressing maintaining the pad in place complete the operation.

At the first dressing, when the drains are removed, the position of the heel pad should be carefully checked.

The Lower Leg.—Tibial stump length of $6\frac{1}{2}$ to 7 inches is ideal; even $4\frac{1}{2}$ inches of bone length will give good function. But stumps with less than 2 inches length below the medial hamstrings are seldom effective. Near or at the hamstring level, full end bearing

may be obtained by fitting with the knee flexed 90 degrees, using a laced socket.

The flaps should be broad, not pointed, the posterior one short, the anterior of medium length. The fibula is exposed by a posterolateral extension of the flap incision. Include the deepest layer of the superficial (fatty) layer in the incision. The treatment of the muscle, periosteum and so on has been previously described. The months so commonly necessary before fitting the prosthesis to lower leg stumps often have their basis in the trauma to the soft parts at operation. Expose the fibula in the muscle plane, sharply cutting the muscular and septal attachments; remove the periosteum from above the level of osteotomy. A Gigli saw obviates much retraction. Cut the fibula off 1 to 2 inches above the tibial site. Smooth the corners well. In short lower leg stumps it is often advisable to remove the entire fibula. When there is question as to the infectious status of the tissues do not do so, since the knee joint may be infected by continuity.

There have been many unsatisfactory lower leg stumps. Some experienced surgeons believe an end weight bearing lower thigh stump, particularly the Gritti-Stokes, is preferable in the long run to even a good lower leg stump. Generally the performance over many years of a good lower leg stump with a well serviced prosthesis will permit no needless sacrifice of the knee joint.

Amputations at the Knee and Distal Thigh.—Good condylar, Gritti-Stokes, capsuloplastic (Callander) and tendinoplastic (lower third) stumps permit considerable to complete end weight bearing.

All end bearing stumps at the knee and lower third must have a posterior scar. Owing to the retraction of the hamstrings and the nonretraction of the relatively fixed quadriceps muscle, even the circular open method will result in a posterior scar if sufficient soft tissue is present.

Even the time honored long anterior flap of the Gritti-Stokes amputation appears unnecessary after using a circular or oval incision with less dissection and vascular disturbance.

The method of condylar amputation as shown by Perry Rogers has given excellent end bearing stumps. In suitable cases it appears that the previously somewhat discredited condylar amputation at the knee merits serious consideration. The outside knee joint of the prosthesis presents an esthetic objection as with other excessively long thigh stumps.

Gritti-Stokes Method.—The essential feature of a good stump by this method is covering the bone end with an intact anterior flap of weight bearing skin, subcutaneous tissue, prepatellar fascia and the anterior portion of the patella, which should unite to the end of the femur. Usually a long anterior and a short posterior flap are formed. It is not necessary or desirable to dissect the skin and subcutaneous flap from the underlying patellotendinous flap. Saw off the posterior articular half of the patella before sectioning the femur. Section the femur at (not above) the level of the upper pole of the patella as noted with the anterior flap lying in its natural position. This is at the upper part of the flare of the femoral condyles. The patella will then naturally lie over the end of the femur. It should not drop posteriorly as when the femur is cut too short. Minimal dissection of the tissues from the femur will

minimize lateral mobility of the patella and help prevent lateral dislocation postoperatively. The patella may be sutured to the femur through drill holes or to the popliteal fascia and hamstring tendons. In any event, check the position of the patella every few days until fixation in good position occurs. Manually replace it if displaced, and maintain position by suitable bandaging. Rebandage as the effusion subsides.

Poor stumps and outright failures result from faulty selection of cases, interference with the circulation of the flap from excessive dissection and undercutting, faulty bone length and a loose wobbly pad of soft tissue and patella.

Tendinoplastic Method.—Excellent stumps, many of which are quite capable of end bearing, are obtained by bone section in the lower third with the soft tissue incision at the patellar level. The circular incision is ideal. Short square flaps take care of the ears if annoying to the surgeon but tend to lead to unnecessary dissection.

Middle Third of the Thigh.—As the more muscular portion of the thigh is approached, short anteroposterior flaps of gradually increasing length are very useful in reducing the trauma incident to the exposure and section of the femur. At a suitable more distal level the knife is carried through skin, fat and deep fascia, including the muscular fascia. With freeing at the septums the muscle bellies are exposed at a higher level, where they are sectioned circularly, each layer being allowed to retract before going deeper. As the deeper layers are cut they retract less and less. The exposed bone is sectioned by means of the aperiosteal technic. The great vessels are exposed in their fascial channels, doubly clamped and cut as the sectioning of the muscle proceeds. On closure, no muscle flap is turned over the bone stump. Owing to the absence of a large traumatized muscle mass, interrupted fine fascial and skin sutures are all that are necessary. The stump is well shaped. There is no muscle mass to shrink slowly. There is no blob of soft tissue at the end of the stump.

AMPUTATION STUMPS OF NECESSITY AND COMPROMISE

Doubtless many a surgeon has been surprised, after performing an amputation of necessity on leaving the stump open or compromising on selection of soft tissues and the location of the scar to preserve length, to find the stump serving very well from a prosthetic point of view without a secondary plastic operation, let alone a reamputation.

Simple procedures are often best. While life saving amputations should not primarily be concerned with securing a permanent stump, there is no need to sacrifice healthy tissue, useful length or leave a projecting bone end.

The circular or oval incision with muscle and bone cut at higher levels many times results in good functional stumps. The surgeon should be aware at the time of the emergency amputation that healing time, dressings, pain and disability are reduced by this method of open amputation.

The principle of traction in controlling retraction of tissues so well proved in the short sleeve of the stepped guillotine or circular amputation should likewise be applied to closed cases in which the soft tissue closure needs relief from tension. The splinting of traction

utilizes the principle of rest in wound healing. Rest should be afforded closed stumps as well. A light plaster of paris bandage is excellent, being efficient, convenient and easy to apply.

It is urged that these simple principles be utilized more in the closed method as well.

RECAPITULATION

Poor stumps often result from surgical errors:

1. Wrong choice of level and type of procedure.
2. Excessive soft tissue dissection, periosteal stripping, trauma, strangulation ligatures and sutures.
3. Soft tissue closure under tension.
4. Redundant soft tissue.
5. Failure to use the open method when in doubt as to circulatory status and infection.
6. Failure to utilize traction or splinting.
7. Neglect of postoperative conditioning of stump, joints, muscle and skin.

Good stumps are made by good surgery:

1. Amputate through viable tissue, neither losing probably useful length nor risking the patient's life in attempting an elective closed amputation when a simple circular open amputation will conserve both.

2. Incise directly through each layer of tissue, the skin, fat and muscular fascia, the muscle, periosteum and the bone at successive levels, not slicing or undercutting or making extensive flaps. Freeing of connecting tissues of the several layers as at intermuscular septums is desirable. Cut the periosteum cleanly, leaving no shreds or flaps behind, and no spurs will form. Leave the bone end with a blood supply and avoid a ring sequestrum. Gentle retraction diminishes postoperative swelling. Careful hemostasis and minimal tissue within ties and sutures shortens postoperative healing and reduces circulatory disturbances. The stump will shrink less and hold up better.

3. Avoid tension; it prevents free circulation. This is a basic surgical principle. Long flaps are not necessary. Plan to have the correct ratio between soft tissue and bone length; don't leave it up to traction, handy stump saver that it is.

4. Trim excessive soft tissue off now; it will save doing it later.

5. Use the open method in cases of infection or potential infection. Healing is often rapid. Many stumps will be good without further surgery. If not, secondary closure, plastic operation or reamputation will make them so.

6. Use traction to maintain soft tissue length beyond the bone. Contracting granulation tissue will do the rest. When traction is unnecessary, a light plaster bandage rests the part—it heals better.

7. Use active motion as healing permits; it improves circulation, frees joint motion, builds muscle. Use an elastic bandage for congested stumps. Graduated friction and pressure accustom the stump to its next job—a prosthesis for weight bearing as soon as possible. The skin must be kept clean; soap, water, air and sun minimize minor cutaneous infections. Early graduated weight bearing on a well fitted prosthesis builds a healthy tough dermis. Don't abuse it.

Ashburn General Hospital, McKinney, Texas.

TEMPORARY PROSTHESES

LIEUTENANT COLONEL T. CAMPBELL THOMPSON
MEDICAL CORPS, ARMY OF THE UNITED STATES

The interval of time which elapses between the loss of an extremity and the application of a permanent prosthesis is a very difficult period of physical and mental adjustment. Anything that can be done to shorten this period and make the adjustment simpler, more rapid and more complete is well worth while.

All factors which tend to establish early painless weight bearing should be understood and applied. Operative and postoperative methods which provide a well healed painless stump as rapidly as possible are of primary importance. Early weight bearing is essential in toughening up a stump to make it fit for prolonged weight bearing. The accompanying illustrations will show some of the things that can be done to obtain a satisfactory stump, and various types of temporary

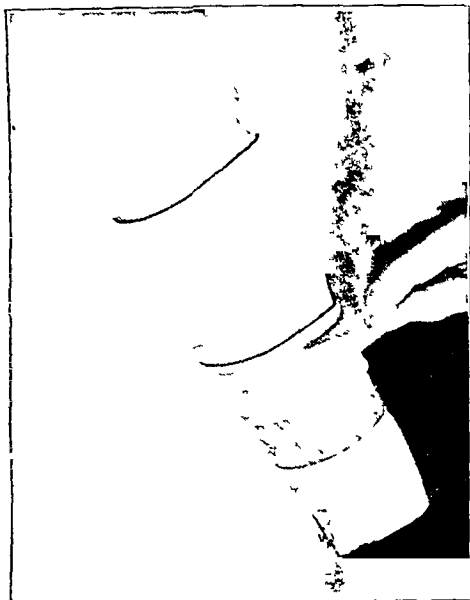

Fig 1.—Applying stockinet and cardboard for building pylon.

prostheses will be demonstrated to show what can be done to provide amputees with walking appliances shortly after their stumps are healed.

Following the practice developed after the last war, it has been the policy at Walter Reed General Hospital to order an adjustable fiber leg (which compares quite favorably with the standard permanent legs on the market) as soon as the amputee is admitted, or when an amputation is performed. The leather bucket or socket for this leg is made as soon as the stump is well healed. As the leg shrinks, a new socket is made whenever the old one becomes too large. When these well made, easily changed fiber legs are not available, temporary plaster pylons are most valuable in toughening up the stumps and shortening the period during which the patient is entirely dependent on crutches.

The first question that a patient asks after losing a leg is "Doctor, when shall I get my new leg?" The mere act of measuring a patient for a leg, and his knowing that it is being made, cause him to look forward to brighter days instead of spending his time bemoaning his lot.

This paper, in a symposium on "Amputations," is published under the auspices of the Section on Orthopedic Surgery

A recent convoy of patients who had been transferred from one hospital to another, during their evacuation, were primarily interested in getting furloughs to see their families. The amputation patients, however, were primarily interested in "When shall I get my leg?"

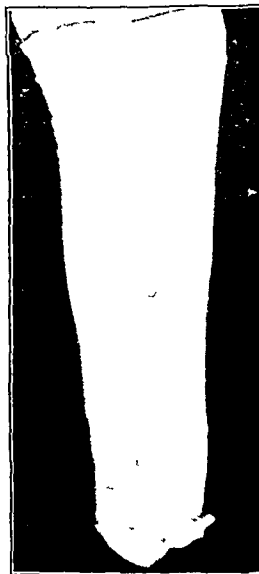

Figure 2.

Fig. 2.—Stockinet pulled down over cardboard. Ready for application of plaster cast.

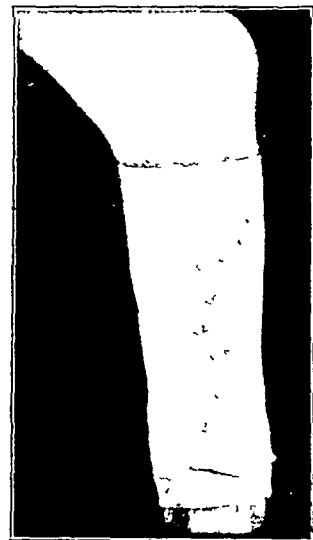

Figure 3

Fig. 3.—Plaster applied, forming socket for pylon.

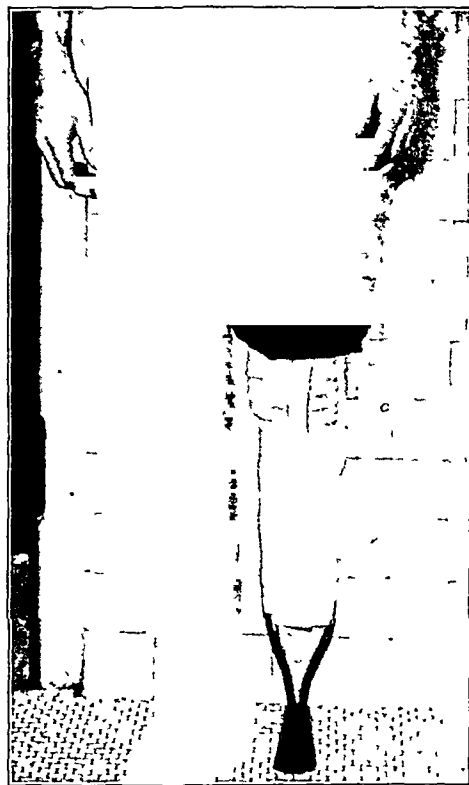

FIG 4—Plaster socket incorporated into walking iron with crutch tip

Measurements were taken and, while their legs were being made, short furloughs were granted, sometimes with the patient on crutches, but often on a temporary plaster pylon.

The following instances of war casualties illustrate three of the more important points:

1. Well healed satisfactory stumps should be obtained as soon as possible.

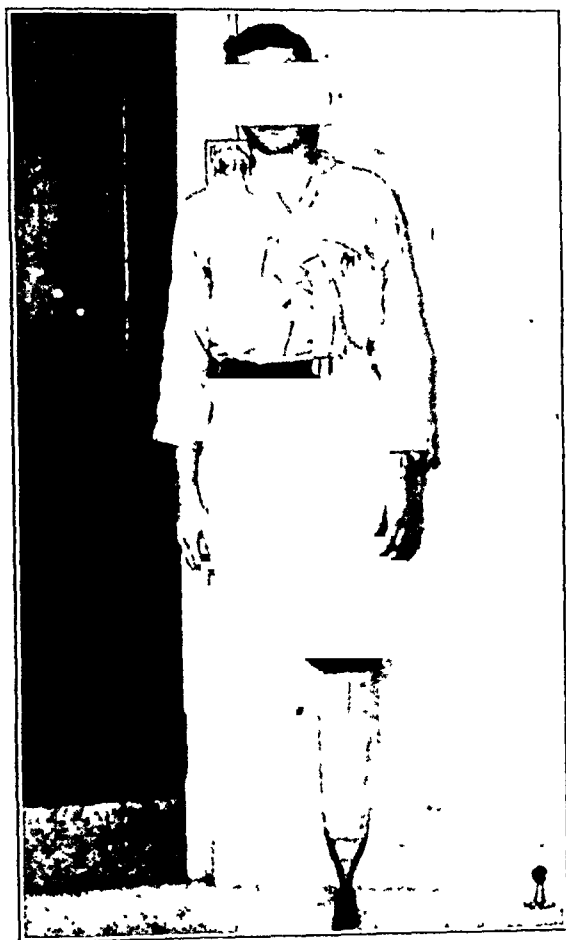

Fig. 5.—Patient walking to toughen up stump.

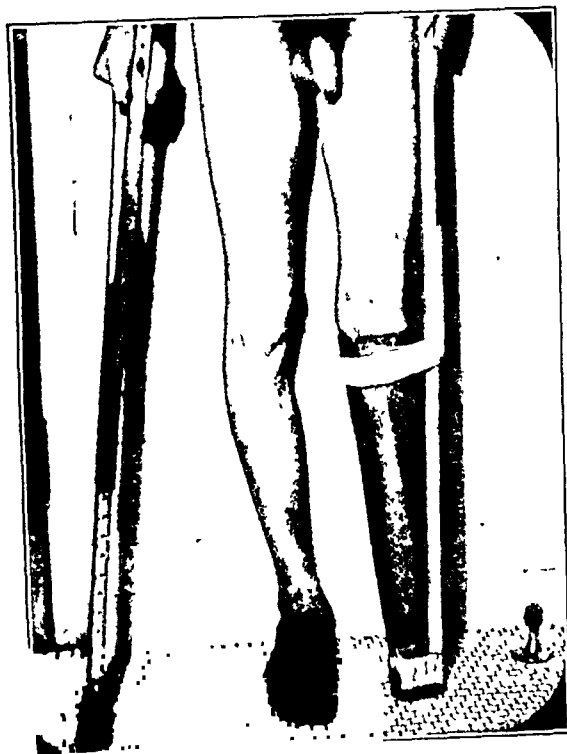

Fig. 6.—Crude temporary cardboard prosthesis.

CASE 1.—An aviator who crashed in Greenland had both feet frozen so badly that they sloughed off. The patient could not be reached and evacuated until eighty-eight days after the accident. Immediate midleg amputations were done and legs fitted as soon as the stumps were healed.

2. Amputations should be of the guillotine, or open, type (especially in wartime), but traction applied at the time of amputation is absolutely essential in order to obtain a satisfactory stump. Cases 2 and 3 show what happens when this important postamputation treatment is omitted. Case 4 shows how readily a good stump can be obtained if constant traction is used.

CASE 2.—A soldier aged 21 received a severe compound fracture of the right lower leg from artillery fire on Nov. 8, 1942. The circulation in the foot was inadequate, and a guillotine amputation was performed on November 11. No traction was used. On admission to Walter Reed General Hospital there was pronounced retraction of the skin. An effort was made on December 10 to save the knee by removing the fibula and freeing the skin; as satisfactory skin could not be obtained over the end of the stump by this procedure and because severe phantom limb pain persisted, a supracondylar amputation was done on Jan. 7, 1943. The phantom limb pain was eliminated and a satisfactory stump was obtained.

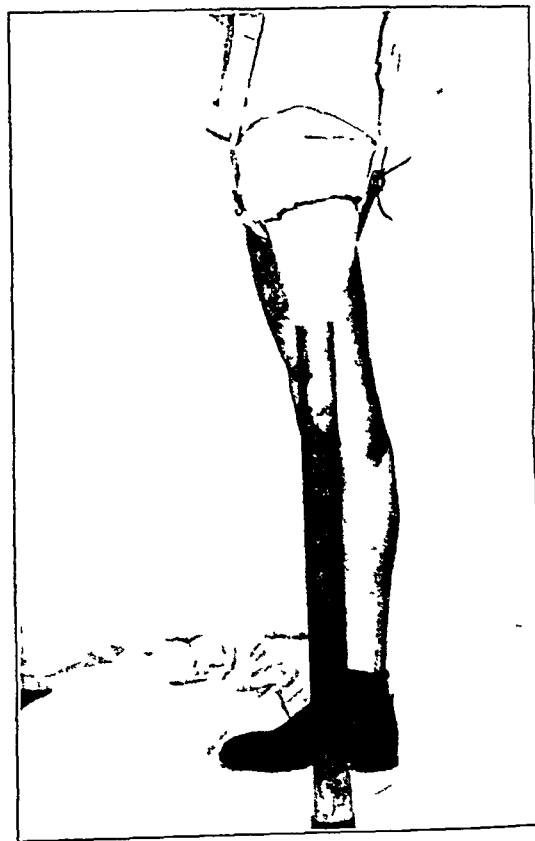

Fig. 7.—Lateral view of temporary pylon.

CASE 3.—A soldier aged 23 received a high explosive wound in the left popliteal space on Nov. 10, 1942. Five minutes later a hand grenade was tossed into his shell hole, and the explosion produced a traumatic amputation of the right lower extremity just above the knee. A débridement was done the same day, but no traction was used until November 28, when he was admitted to Walter Reed General Hospital. Bone and soft tissue protruded 3 inches beyond the skin margins. After three weeks of constant traction the skin had come down even with the end of the bone. After six weeks of traction the bone was well covered. A plastic closure was done on Jan. 20, 1943, and a good stump obtained.

CASE 4.—On Nov. 8, 1942 a soldier aged 26 received a gunshot wound of the left thigh which injured the popliteal artery. Gangrene of the foot and leg developed, and a low thigh guillotine amputation was performed on November 13. Constant skin traction was used. Three weeks after amputation the condition of the stump was excellent.

Traction was used together with a small wooden spreader to produce a transverse instead of a circular scar. Healing and contraction of the scar under seven weeks' constant traction was rapid. The patient was allowed up on crutches during

the day, but traction was constant. A complete closure of the stump was done on Jan 14, 1943, just two months after the injury.

3. Temporary prostheses are most important in toughening up the stumps and preparing them for permanent legs.

Figure 6 shows an ingenious and extremely simple type of prosthesis that was used in the Danish Hospital in Paris during the last war. A heavy cardboard cornucopia is attached to a wooden stick. The patient uses this as a cane but bears some of his weight on his stump. It is laid aside when he sits down.

Fig 8—Permanent upper and lower extremity prostheses fitted. Patient ready for rehabilitation.

The various steps in making a plaster pylon for a below knee stump are shown in figures 1 to 5. (Incidentally, this stump was too long, and reamputation was done later.)

Plaster pylons for thigh stumps are made in a similar manner.

The adjustable fiber prostheses which are ordered at the time of amputation are shown in figure 10. They are strong, durable and inexpensive. The removable leather buckets can be made and the entire leg fitted and adjusted as necessary by any well trained brace maker, preferably one with some experience in artificial legs. These prostheses function practically as well as high priced willow or aluminum legs.

CASE 6.—A soldier aged 23 picked up two 37 caliber duds on April 11, 1941; an explosion blew off all the fingers of his right hand and produced a compound fracture of the left femur in the lower third. The right hand was amputated at the wrist.

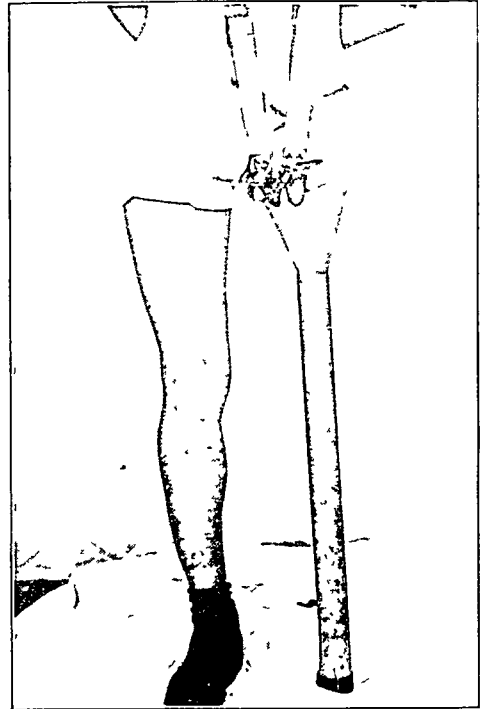

Fig 9—Temporary pylon for short thigh stump

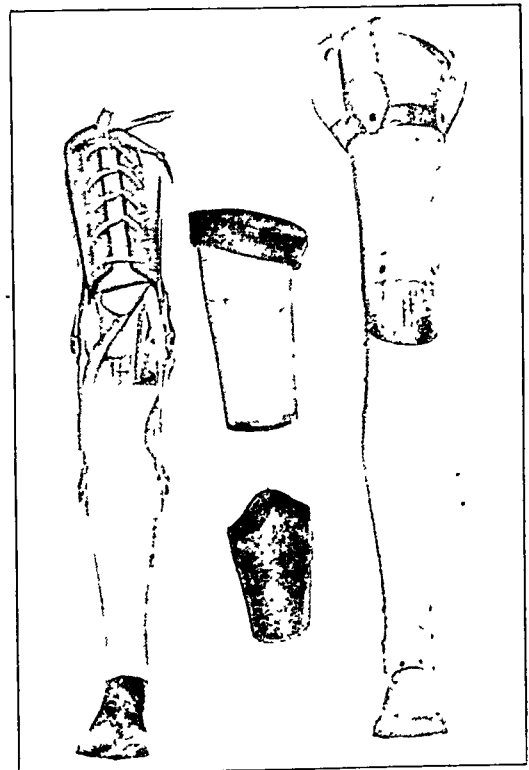

Fig 10—Adjustable fiber prostheses with molded leather sockets for leg and thigh stumps.

and the left femur was treated with Roger Anderson pin fixation. Because of intensive infection of the fracture site and the pin wounds, a high guillotine amputation was performed on August 29. A partially successful skin graft was performed

on October 27. The patient was admitted to Walter Reed General Hospital on June 26, 1942 for the treatment of a very short, painful left thigh stump with an adherent terminal scar and a right arm stump too long for a prosthesis. The right arm was reamputated and a plastic procedure performed on the left thigh stump. The temporary peg leg (on which the patient walked very well) and the final arm and leg prostheses are shown in figures 7, 8 and 10.

THE PERMANENT PROSTHESIS

ATHA THOMAS, M.D.

DENVER

Modern skill has brought no more useful aid to humanity than the artificial limb, or prosthesis, which transforms a helpless dependent into a useful member of society. The modern limb maker is a highly skilled artisan who is eager to aid the surgeon in the rehabilitation of his patient. He belongs to an old and honorable guild with a record of fine service and with a high code of ethics, designed to prevent exploitation of

the handicapped by the unscrupulous. Such a code of ethics is subscribed to by the Association of Limb Manufacturers of America. This organization is doing a splendid work through its educational and research program in advancing knowledge and skill in the manufacture and fitting of artificial limbs.

It should be the responsibility of the surgeon to advise the patient as to his permanent prosthesis and to supervise the fitting of the appliance. Many otherwise competent surgeons, through ignorance, prejudice or lack of interest, fail to accept this responsibility and dismiss the patient as soon as the stump is healed, with little or no advice as to the permanent prosthesis.

The surgeon need not have an intimate knowledge of the details of the materials and construction of the artificial limb. He should, however, be sufficiently familiar with the various types

Fig. 1.—Conventional prosthesis for midcalf amputations. The weight is borne largely on the sloping surfaces of the tibial condyles, anteriorly and laterally.

of limbs available and should have some knowledge of the standard types of joint control mechanisms. He should know enough about the fitting of appliances to

This paper, in a symposium on "Amputations," is published under the auspices of the Section on Orthopedic Surgery. The executive officers of the Association of Limb Manufacturers of America gave generous help in furnishing data and models.

recognize it as a skilled art and advise his patient as to the advantage of a personal fitting at the place of manufacture.

The emotional disturbances accompanying the loss of a limb are often serious, and the necessary adjustment to the loss is difficult for some patients. This problem

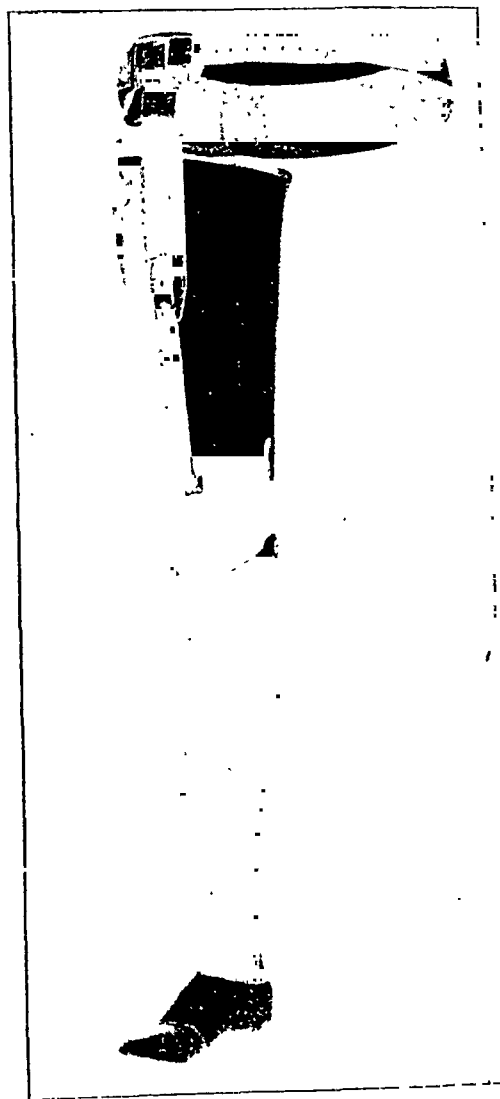

Fig. 2.—Conventional prosthesis for midhigh amputations. Weight bearing is carried almost entirely from the ischium. Note the "muscle strap" of leather and elastic which controls knee motion.

of emotional adjustment is made much easier for the patient if he realizes that the surgeon continues interest in the case even after the stump is healed and is willing to assume some responsibility in advising him concerning the permanent prosthesis and in supervising its fitting.

Personal acquaintance with the limb maker on the part of the surgeon and willingness to work in close cooperation with him inspire confidence on the patient's part and aid him in an otherwise difficult adjustment. The shorter the period between amputation and prosthesis, the easier the adjustment is likely to be. Unnecessary delay results not only in faulty psychologic adjustments and habits but in joint contractures and atrophy of the stump.

The skill and care with which an amputation is performed and unremitting attention to the postoperative care are tremendously important factors in hastening the time when the permanent prosthesis can be applied. The advantages of the temporary prosthesis in hastening the shrinkage and toughening of the stump have already been discussed by Major Thompson.

THE STUMP

The most important requirement for a comfortably fitting, efficient limb is a properly formed stump. Improperly placed operative scars, deficient or excess bone length, redundant muscle, tight skin flaps and exposed nerve ends all tend to make fitting difficult and weight bearing and locomotion fatiguing and painful.

CONSTRUCTION OF PROSTHESIS

The standard construction of an artificial leg usually consists of the (1) socket, (2) knee piece, (3) shin piece and (4) foot.

The socket is that portion of the limb into which the stump is fitted. It is usually constructed of willow or basswood, carefully cut out to fit the contours of the stump. The wood socket is covered with tightly stretched rawhide, which greatly adds to its strength. Leather and fiber are also used for the socket. Some metal and some plastic sockets have been made but are not in general use. Aluminum alloy makes a light and durable limb but is more expensive and is not readily available now.

The knee piece is an important control mechanism allowing knee motion with stability. The proper fitting

and alinement of the knee joint axis is of the utmost importance. Side joints at the knee are used in amputations below the knee. Should these joints be placed too far anteriorly, pressure will result in the popliteal space, causing edema of the stump. Stability and control of the artificial knee joint and the prevention of buckling, or "jackknifing," in thigh amputations are provided by various ingenious devices. It is not necessary to give a detailed description of all these mechanisms. Knee motion is usually controlled by a "muscle" strap of leather, with elastics on either end, which is attached to the pelvic belt and passes over a roller fastened to the shin piece inside the knee. As the knee is flexed, pressure is applied to the control strap pulling the shin piece forward for the next step. Knee joint control is also effected by the proper setting of the

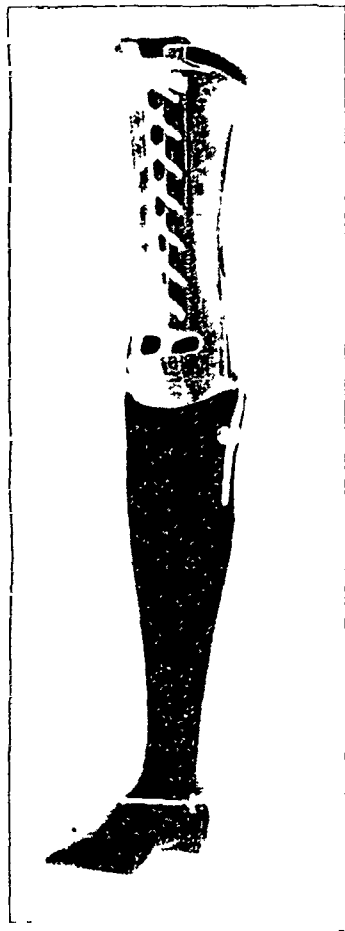

Fig. 3—Prosthesis for end bearing stump at the knee of the Gritti-Stokes or Rogers type.

joint axis. The farther posterior the axis is set the more positive is the knee lock when weight is applied.

The foot in most general use today is made of wood with a joint in the forefoot of rubber belting and with limited motion at the ankle. Rubber pads or bumpers

are placed in heel, instep and forefoot. The position and thickness of these rubber pads in the foot also affect the stability of the knee joint. Increasing the "fixed equinus" of the ankle by raising the front pad in the instep tends to throw the knee into hyperextension and increases knee joint stability.

COMMON TYPES OF
PROSTHESIS FOR
AMPUTATIONS
AT VARIOUS
LEVELS

End bearing stumps are successful only in the region of the ankle and knee. These amputations are very popular in Canada and, according to Gallie, are much preferred there to midcalf and midhigh amputations. They are not so popular in this country or Great Britain. Limb makers object to them because of difficulties in making a prosthesis that is comfortable and that conforms to the shape and length of the opposite limb. Another difficulty encountered with a prosthesis for the Syme amputation is preserving sufficient strength at the ankle to take care of the excessive strain when weight is borne on the ball of the foot.

In midcalf amputations the weight is borne largely on the sloping surfaces of the tibial condyles, avoiding pressure in the popliteal space. The stump should be fitted into socket with the knee slightly flexed, causing more weight to be carried forward over the anterior portion of the tibia.

With amputations through the knee joint of the Gritti-Stokes or Rogers type, weight is carried on the end of the stump and on the sloping surfaces of the thigh. The socket for such a stump is usually made of heavy leather with a front opening for lacing and with a felt pad on the end for weight bearing.

Weight bearing in thigh amputations is carried almost entirely from the ischium. Some weight may be taken on the sloping surfaces of the thigh, but all pressure on or near the end of the stump must be avoided. Undue pressure must also be avoided in the adductor region. Pressure boils in this area are common as the result of an ill fitting ischial seat. In this type of limb, suspension by a pelvic band with a joint at the hip and with direct stump control seems to be most generally favored, although some patients find shoulder straps preferable. The majority of limb makers recommend a rigid type of hip joint control with no lateral motion.

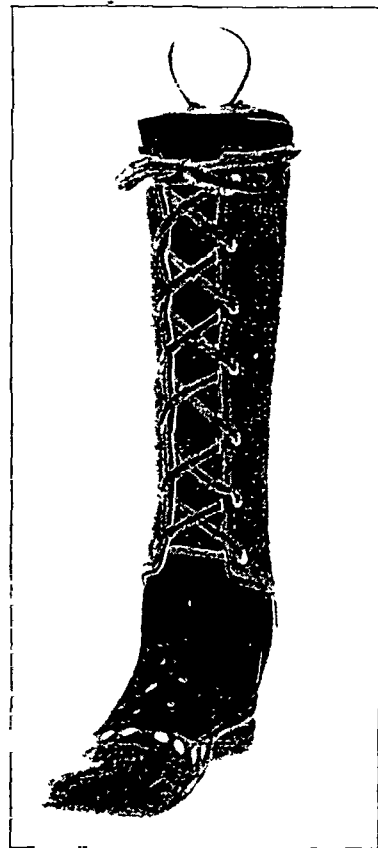

Fig. 4—End bearing prosthesis for the Syme amputation through the ankle.

Artificial limbs for hip joint disarticulation offer a difficult problem. If sufficient muscle about the hip is preserved so as to give a good seat, a conventional type of above knee limb with a saucer shaped socket can be successfully fitted. If the amputation does not permit this type of prosthesis, then a bucket type socket or a "tilting table" prosthesis must be used. A hip lock is always necessary with this type of appliance and in most cases a knee lock as well.

Fitting of Prosthesis and Care of Stump.—Careful fitting and alinement of the limb and instruction of the patient in its proper use are of utmost importance. The stump is protected by a woven stump sock of virgin

Fig. 5.—Conventional type of upper extremity prosthesis equipped with a mechanical hand, interchangeable with a utility hook, and controlled by straps from the opposite shoulder.

wool. One, two or more of these socks are worn, depending on the amount of shrinkage that takes place in the stump. The socks should be changed daily and kept scrupulously clean to avoid skin irritation or infection.

Upper Extremity Prosthesis.—The use of prostheses in amputations of the upper extremity is not nearly so satisfactory as is the lower. The successful wearing of such a prosthesis depends not only on the character of the stump but on the psychologic adjustment of the patient in learning to use it. The most successful prosthesis is that fitted to a short forearm stump and equipped with a mechanical hand, interchangeable with a utility hook and controlled by movements of the opposite shoulder.

CONCLUSIONS

It should be emphasized that in the successful fitting and use of prostheses not too much importance should be placed on the particular type of limb, materials used or certain special features, such as complex joint controls. The more important considerations from the point of view of both patient and surgeon are whether the socket properly fits the stump and whether the limb is well constructed and of proper alinement and length.

Success in the rehabilitation of a person crippled by the loss of a limb depends first on a well performed amputation with a stump of proper contour and length, and finally on the closest cooperation between the surgeon and a skilled, ethical limb maker in the selection and fitting of the permanent prosthesis.

1612 Tremont Place.

ABSTRACT OF DISCUSSION

ON PAPERS OF MAJOR GENERAL KIRK AND LIEUTENANT COLONEL MC KEEVER, COMMANDER WHITE, MAJOR V. P. THOMPSON, LIEUTENANT COLONEL T. C. THOMPSON, AND DR. THOMAS

LIEUTENANT COMMANDER HARRY B. MACEY¹ (MC), U.S. N.R.: There will be an immediate need for a great number of amputations in a late teen and early adult age of men—a group in which close relationship between the surgeon and the patient may play a most important part. In the military service the medical officer is looked on with respect and, at times, admiration, thus creating an ideal condition for encouraging early rehabilitation of the crippled serviceman from both a mental and a physical standpoint. The guillotine amputation with the operative procedure and postoperative care, the details of which are a result of much experience, need only to be followed to obtain good results. The clinical observations referred to in 150 amputations, including those on patients from all theaters of operations of the present war and performed under various conditions and by surgeons of varying experience and ability, are self explanatory and should be sufficient proof of the value of, and at times the necessity of, the guillotine operation. The article referring to the amputation stump from the prosthetic point of view should be carefully read by every surgeon and medical officer who anticipates that he might be called on to perform an amputation. In the elective midcalf or below-knee amputation, fixation of the fibula to the tibia, accomplished by roughening the lateral and medial aspects of the bone ends of the tibia and fibula respectively and transfixing the fibula to the tibia by use of a vitallium screw, will prevent the chance of a floating fibula, which at times detracts from the usefulness of the stump by its mobility. The use of the temporary prosthesis has not been sufficiently stressed in the past, but its advantages are manifold and should be routinely employed, especially in young amputees. An additional temporary prosthesis not offered in the symposium, but which may be used advantageously, is the use of a well padded plaster of paris socket attached to a crutch at the level of the amputation. This encourages early physical activity and mobilization in weight bearing of the recently amputated extremity. The opening statement in the discussion on pain after amputation and its treatment should serve as a warning to those attempting to relieve phantom pain unless they have a deeper insight into the subject than is generally understood. The list of nonbeneficial procedures suggested should be carefully reviewed so that useless procedures will be avoided. The only procedure which should be employed, save in the hands of one experienced in this field of surgery, is the single resection of a neuroma when it is shown to be indicated.

DR. PHILIP D. WILSON, New York: The number of amputations performed each year among the civil population of our country far exceeds that in the Army during the last war or

1. This discussion has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the U. S. Navy. The opinions and views set forth are those of the writer and are not to be considered as reflecting the policies of the Navy Department.

the number that may be anticipated among our armed forces during the present war. The artificial limb manufacturers of the United States report that in 1942 they supplied limbs to approximately 70,000 civilians, whereas the total number of amputations in our army during World War I was about 4,000. There is, therefore, as much need for improvement of knowledge among surgeons and limb makers in time of peace as in time of war. War conditions, however, impose a different outlook on surgeons from those of peace with regard to how amputations shall be done. While the requisites of a good amputation stump remain the same, different methods must be employed to obtain them. In the combat zone, where surgery must often be done under primitive conditions and the patients must be evacuated rapidly over considerable distances to hospitals in the rear, it is obviously unsafe to suture wounds of any type, including amputation stumps. The same applies to amputations that are performed in the presence of infection, wherever they may be done. General Kirk and Colonel McKeever present sound arguments for the use of the guillotine method and they rightly emphasize the importance of skin traction in the after-treatment. The senior author treated many hundreds of amputations in the last war and no one is better qualified than he to give an opinion of the good results that may be achieved by these methods when properly used. I am in complete agreement with the conclusions of these authors and I would like to emphasize particularly the necessity of applying skin traction to the stump continuously from the time of amputation until healing is achieved. The most serious cause of interruptions of such treatment in the present war is the evacuation of patients from one hospital to another over long lines of communications, finally terminating in a voyage over seas. These difficulties should be overcome by the use of the Thomas splint to provide fixed points of traction and counter traction or if the patient is ambulatory by the application to the stump of a plaster bucket in which is incorporated a heavy wire frame to provide a point of fixation for the traction. Now that skin grafting is being employed so successfully for the early closure of granulating wounds, a word of caution is necessary about the use of this method to close amputation stumps. A skin graft will never tolerate the stresses caused by the use of an artificial limb, and excision of the graft with plastic closure of the skin will be required. But the application of the graft interferes with the normal process of scar contraction, which is relied on together with skin traction to pull the normal skin down over the end of the stump. Closure by skin grafting is therefore likely to result in greater difficulty for the surgeon when he attempts later plastic closure than when natural healing is allowed to take place. Continuous skin traction is a better method for obtaining healing than skin grafting and will require only a slightly longer period of time. There is no point of disagreement with Major Thompson. I would emphasize the need for judgment in choosing the level of amputation and particularly would point out the advantages of the Syme, Gritti-Stokes or tendinoplastic amputations when possible. These stumps are capable of direct end bearing and will stand heavier service with greater comfort to the patient than many other types of amputation of the lower extremity. Commander White considers the painful neuroma of little importance in causing intractable pain and gives chief attention to the surgical methods that attack the central nervous system at higher levels in order to obtain relief. Certainly all surgeons who have had experience in the treatment of painful stumps will agree that there are many cases in which pain persists even after the removal of all possible local or peripheral causes and where they have been at a loss how to give relief. In presenting the other surgical methods that may be used and the results that have been obtained, Commander White has made a real contribution. The discussion of temporary and permanent prostheses by Lieutenant Colonel Thompson and Dr. Thomas emphasizes the objective of all surgery, which is to produce a stump capable of optimum function with an artificial limb. Only the surgeon who is familiar with the construction and mechanical principles of these limbs is capable of doing this, but unfortunately many surgeons are called on to perform amputations in

an emergency who do not have this knowledge. It is their duty to familiarize themselves on these points in order that their surgery may not only save their patients' lives but give them utmost comfort in the years that follow. Finally I should like to express the opinion that the system of temporary prosthesis now being used by the Army, which was reported by Lieutenant Colonel Thompson, represents the best that can be done for our soldiers with amputations and is far superior to the peg legs fitted with plaster of paris sockets which were used so extensively during the first world war.

DR. J. ALBERT KEY, St. Louis: The guillotine amputation has stood the test of time as a saver of life and length of limb in military surgery. This is not a severance of the limb, such as would be made by a guillotine, but is one which leaves the fresh stump with a square end. When traction is applied to the skin this square end becomes a shallow funnel with the end of the bone at the bottom. This traction should be applied at the time of the operation and continued even during transportation if possible until the scar is well contracted and fixed to the end of the bone. This is especially important in short stumps. The amputation should be performed at the lowest level permitted by the viability of the tissues, and this applies to the hand and foot as well as to the cylindric portions of the extremity. The surgeon who performs the primary amputation saves the life of the patient, prevents spreading infection and saves as much of the extremity as possible. The surgeon who performs the secondary operation selects the level of the amputation and so fashions the stump that he gives the patient the best possible result. The final amputation or plastic closure of the stump is an operation which requires a high degree of surgical judgment and skill. Our Army has recognized this fact and has met the problem by establishing five amputation centers, in each of which the amputation service is headed by a surgeon who has developed the required judgment and skill. The patients are transferred to one of these centers for the final operation and the fitting of the prosthesis. At a recent conference on amputations by representatives from Great Britain, Canada and the United States the experiences of the armed forces were pooled for the benefit of all. The Canadians are partial to end bearing stumps (Stokes-Gritti and Symes). The English dislike long stumps on account of circulatory disturbances and use ischial bearing prostheses for most of their below knee amputations. I prefer a slightly longer stump and take most of the weight on the sides of the below knee stumps. Muscle and tendon plastic stumps are largely abandoned, and the end of the bone is covered only by skin and fascia. Excess muscle is excised and permitted to retract in order to give a conical stump. But in plastic closures on guillotine stumps the muscle should not be freed from the bone because this stabilizes the tissues and, as Col. T. C. Thompson has noted, often gives a better stump than is obtained by an elective amputation. Excessive tension on the skin flaps is to be avoided but, if unavoidable, can be neutralized by skin traction, which is continued until the wound is healed. The temporary prosthesis supplied by our Army is really an excellent artificial leg fitted by experts, and our patients are fitted and taught to use their limbs with as little loss of time as possible. Dr. Atha Thomas has emphasized the cooperation which should exist between the surgeon and the limb maker and has noted that the surgeon's responsibility is not ended until the patient is fitted with a satisfactory limb. Attention should be called to the facts that not only is the Association of Limb Manufacturers of America conducting a research program but its members have unselfishly pooled their patents in order that the best possible prostheses may be available. I can say little about postamputation pain except that it is now believed that the important nerves should be drawn down slightly and cut cleanly across and permitted to retract. Ligation, injection with alcohol or crushing of the nerve before cutting is discouraged. If phantom pains appear, it is possible that early injections of the peripheral nerves or of the sympathetic ganglions with procaine hydrochloride as recommended by de Takats and Miller (*Arch. Surg.* 46:469 [April] 1943) may prevent much later pain and disability.

CHRONIC MALARIAL PARASITEMIA IN
ITALIAN PRISONERS OF WARCAPTAIN STANIS P. CARNEY
SANITARY CORPS, ARMY OF THE UNITED STATESAND
CAPTAIN NOAH B. LEVIN
MEDICAL CORPS, ARMY OF THE UNITED STATES

The internment of prisoners of war has presented an opportunity to study under closely controlled conditions the incidence of parasitemia in a large group of men who have been returned from an area where malaria is hyperendemic to a malaria-free region.

The present study was initiated in a prison camp with a population of close to 3,000 Italian prisoners of war. About two thirds of these men came directly from the North African area. The remainder came from the same theater, but they had spent three months in another camp before being transferred here. All of them had seen service for varying periods in malarious regions, some as long as ten years, although the average was about two years.

It soon became apparent that malaria was going to be a problem of some concern in this camp, since immediately after arrival of the prisoners cases of malaria began to appear. The first question which arose was the problem of transmission of the disease to the uninfected prisoners, to the army personnel attached to the camp and to the nearby civilian population. This was satisfactorily answered by the results of two mosquito surveys made in the area in which the camp is located, one made by the state university and the other under the direction of the Seventh Service Command, in both of which no anopheline mosquitoes were found. As an added precaution, however, all men hospitalized for malaria were screened by mosquito bars after dusk.

The proposal to send some of the prisoners to work on farms in the region of the camp raised another question. Since, in many cases, side camps were to be set up, sometimes many miles away from army hospital facilities, it was decided to make an attempt to locate all men with parasitemia.

METHODS

Both thick and thin blood smears were made for each man, prepared with Giemsa stain. Thick smears were examined to determine the presence of malaria parasites, and when the number of parasites found was sufficient to make a search of the thin smears practicable these were studied to prove further identification of species. At least two smears, taken two or more days apart, were examined for each man. In addition, at the time the smears were taken every man was asked if he had ever had malaria.

RESULTS

The accompanying tables give a statistical analysis of the results. The breakdown by companies (table 1) has a certain value, in that part of the fourth company, together with the men in companies 5 through 8, came from the other camp, where a number of active cases occurred not included in these results. These men constitute one of three groups into which the camp might be divided, the others being the first four and the last four companies. The men in each group had

fought together and were taken prisoner at about the same time and in the same region. This may account for the fairly high percentage of positive smears in the first four companies as contrasted with the others.

The organisms of all the positive smears were identified as *Plasmodium vivax* except two each of *Plasmodium malariae* and *Plasmodium falciparum*. This agrees with the usually accepted fact that *P. vivax* is the type most likely to recur. Fifty-six cases of active clinical malaria have occurred to date, all proved by microscopic study. A number of recurrences has brought the total number of admissions for malaria to a somewhat higher figure. Thirty-two additional patients transferred from a general hospital overseas with a diagnosis of malaria are not included in the tabulated results since there was no evidence in their records of blood studies and no parasites were found in the blood here.

The onset of cooler fall weather was followed by a striking and abrupt cessation of admissions of men

TABLE 1.—Statistical Breakdown by Companies

Company	No. of Men	No. of Positive Smears	Percentage of Positive Smears	No. of Active Cases	Percentage of Active Cases
1.....	250	49	19.6	13	5.2

Men with positive smears and no history.....	212	8.3

with active malaria to the hospital. The blood smears from the seventh company were taken after this time, and, while only a small group is represented, it is felt that this is reflected in the low percentage of positive smears for those men.

A glance at table 2 will immediately make it apparent that a history of previous malaria was unreliable in this group. It will be noted that 59 per cent of the men with malaria gave no history of ever having had the disease before. A considerably higher figure, 83 per cent, of all patients with positive smears failed to give a history of previous attacks. In spite of the fact that most of these men seemed to know what malaria is like, it is probable that a greater number had had malaria in the past than would be indicated here. Repeated questioning of the hospitalized men sometimes drew out a history previously denied. Yet even after such persistent questioning, over half of the men with active malaria had no knowledge of past infection. While it is probably true that the same repeated questioning applied to all the men would have raised the number who admitted having had the disease, there would still be a large group who would persist in their denial of previous attacks. We do not suggest that the same situation will prevail with American troops. The language difficulty inherent in dealing with prisoners of war makes any such comparison of expected results

This work was done under the direction of the Seventh Service Command.
Lieut. Col. George F. Swanson, M. C., station surgeon at the camp investigated, gave all possible encouragement and assistance.

impossible. American soldiers, furthermore, are thoroughly schooled in the symptoms of malaria, and it is to be expected that they will have more insight for otherwise unexplained symptoms.

Included in the foregoing group are the men who were infected but who had no clinical symptoms until months later. According to their own statements, anti-malarial drugs are not used routinely in the Italian army for prophylaxis in endemic areas. Each man, however, is given a package of drugs to take at the first suggestive symptoms. It would appear, then, that drugs taken under these conditions may increase the incubation period to a much longer time than is usually considered customary and that clinical symptoms will not necessarily appear shortly after the intake of prophylactic medication stops.

It is admitted that this type of study will not find all the cases. At least 1 patient was admitted to the hospital with proved malaria only a week after his blood had been examined and found free of plasmodia. Five men with positive smears were selected at random for more complete study. Two of these eventually came down with clinical malaria; the other 3 never exhibited active symptoms. Smears were examined for these 5 twice a week, and at times parasites could not be demonstrated after the most critical search. In spite of the fact too that no man with active malaria was discharged from the hospital until two consecutive thick smears were negative, there were some recurrences.

CONCLUSIONS

1. Plasmodia may still be demonstrated in the blood months after evacuation from an area where malaria is endemic. In the group investigated this was found true for a fairly large number, aggregating almost 10 per cent.

2. It is possible to find parasites in the blood of a person even though he maintains that he has never had malaria. Where language difficulty is a factor, as with prisoners of war, this may operate to make the presence or absence of a previous history unreliable in selecting men who may have a residual parasitemia.

3. Malaria may be contracted with no symptoms of active disease until months after infection. This is probably particularly true when antimalarial drugs are taken prophylactically, and the symptoms will not necessarily appear when intake of the drugs ceases.

4. No expectation of the residual malarial rate of United States troops can be predicated from these figures. A great many of the Italians grew up in malarious regions and were exposed and infected long before their period of military service, while only a relatively small percentage of American soldiers come from areas where malaria is present in any degree at all. The antimalaria precautions taken for United States troops in the field also serves to keep the incidence of malaria down. An advice from the office of the Surgeon General of the United States Army indicates that the incidence of parasitemia in the absence of clinical symptoms for our returned troops is much lower than the figures reported here for the prisoner group. In spite of these differential factors, we feel that this study emphasizes the necessity for careful examination of blood smears for all personnel who have returned from areas where malaria is prevalent and the need for treatment to sterilize the blood in all cases of parasitemia. This will serve the double purpose of protecting the person from further attacks and of eliminating him as a carrier.

Clinical Notes, Suggestions and New Instruments

ACTINOMYCOSIS OF THE SUBCUTANEOUS TISSUE OF THE FOREARM SECONDARY TO A HUMAN BITE

LIEUTENANT ROBERT A. ROBINSON, MEDICAL CORPS,
ARMY OF THE UNITED STATES

In 1930 Henrici stated that "any suppurative inflammatory reaction which stubbornly resists treatment but tends to discharge continuously should lead one to suspect the possibility of actinomycosis."¹

In the medical literature there are only a few case reports of actinomycosis secondary to human bites.² Perhaps this scarcity of case reports makes one less prone to suspect actinomycosis when dealing with a chronic infection secondary to a human bite than to think of tuberculosis, osteomyelitis or a foreign body reaction.

This case is reported to emphasize the importance of considering actinomycosis as a possible sequela of a human bite.

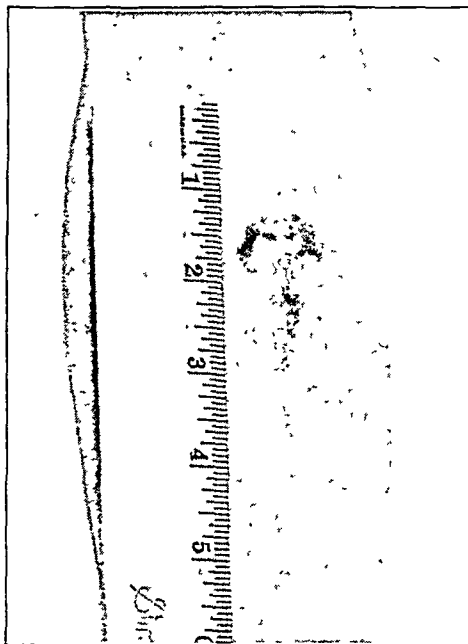

Fig. 1.—Surgical scar with pigmentation.

REPORT OF CASE

R. L. M., a man aged 21, admitted to the hospital March 26, 1943, was not acutely ill but complained of pain and swelling just below the elbow on the left forearm at the site of the human bite which he had sustained two and a half years before. His previous history was one of generally good health except for acute mastoiditis with mastoidectomy at 7 years of age, pneumonia at 8 and scarlet fever at 20. These illnesses had left no obvious disease of any system. Notable injuries were limited to the one which initiated the present illness.

Sept. 7, 1940, while playing volley ball, the patient sustained the human bite wound. He struck his elbow against another man's front teeth. Iodine was immediately poured over the two small tooth wounds, and the arm was bandaged.

Two days later a cellulitis developed in the left arm. A physician made a short incision connecting the two puncture wounds and sent the patient to bed. He received about 4 Gm of sulfanilamide a day for ten days. The arm was elevated, and wet soaks were applied. The cellulitis subsided and the skin wound healed, but the area remained slightly red, indurated and tender.

1. Henrici, A. T.: *Yeasts, Molds and Actinomycetes*, New York, John Wiley & Sons, Inc., 1930.
2. Cope.^a McWilliams.^a

One year after the original wound, during the second recurrence of a localized abscess in this area, a study of pus from the abscess failed to show tubercle bacilli, and x-ray changes of osteomyelitis or of a foreign body in the tissues were not found. No apparent attempt was made to investigate the possibility of actinomycosis.

Acute abscesses recurred at the site of the bite wound whenever it was bruised. These abscesses drained some watery pus and healed spontaneously. There was persistent induration and tenderness of the soft tissues in this area for two and a half years.

On March 23, 1943 the patient bruised the site of the chronic inflammation, and three days later he came to the hospital for surgical relief, no spontaneous drainage having begun.

The patient was 70 inches (178 cm.) tall, weighed 140 pounds (63.5 Kg.) and was of the asthenic habitus. The blood pressure was 115 systolic, 76 diastolic, the pulse rate 80 and the respiratory rate 20. The temperature was 97.8 F. The red blood cells numbered 5,200,000, the white blood cells 12,500, with 77 per cent polymorphonuclears, 15 per cent lymphocytes and 8 per cent monocytes. The Kahn test was negative, and the urine normal. The physical examination was negative except for the left upper extremity. There was a tender, hot, fluctuant, soft

Fig. 2.—Actinomycetes, $\times 100$ (U. S. Army Medical Museum negative number 76449).

tissue swelling measuring 3 by 2 inches overlying the proximal fourth of the left ulna. A $\frac{3}{4}$ inch scar at the site of the original wound lay transversely across the top of the fluctuant area. The surrounding skin was red, but the skin on the top of the abscess was pigmented, light brown and violaceous. X-ray examinations of this area were negative for osteomyelitis, periostitis, a foreign body and soft tissue calcification.

The abscess was opened with the patient under general anesthesia in the operating room, sterile technic being observed. Through a $2\frac{1}{2}$ inch incision in the long axis of the arm about 5 cc. of odorless grayish pus of milky consistency was evacuated, smeared and cultured. Digital examination of the abscess cavity revealed necrotic granulation tissue in which small yellow bodies about 1 mm. in diameter were noted. This tissue was fixed in alcohol. The periosteum and bone underlying the abscess were normal.

A dressing of sulfanilamide crystals and zinc peroxide paste, without packing, was applied to the wound postoperatively and almost every day for three weeks. The wound completely healed in four weeks and no induration, tenderness or heat was discernible in the area four months after the surgical drainage of the abscess. The infection had subsided for the first time in two and a half years. The only residuum was the pigmentation on each side of the surgical scar (fig. 1).

PATHOLOGIC FINDINGS

Microscopic examination of the pus showed no cocci or bacilli but many polymorphonuclear leukocytes and monocytes. The aerobic and anaerobic cultures of the pus were sterile after twenty-four hours and in ten days. It was concluded that the pus offered no clue as to the etiologic agent.

Macroscopic examination of the granulation tissue revealed small yellow specks, which were crushed, smeared and gram stained. This preparation of the sulfur granules demonstrated numerous gram positive, threadlike mycelia with axial filaments, true branching and clubbing about the mycelial tips. These slides were sent to the late Dr. A. T. Henrici, professor of bacteriology at the University of Minnesota Medical School, who reported: "I have examined the smear from R. L. M. and I believe there is no doubt that this is a case of actinomycosis. The smear shows the typical branched filaments of actinomycosis bovis."

The granulation tissue was sent to Letterman General Hospital, San Francisco, where it was sectioned and examined by Major Harold L. Stewart, M. C., pathologist, who reported: "The specimen of granulation tissue is composed of loose fibrous tissue, numerous dilated proliferating capillaries and many inflammatory cells. In one area there is a large, irregular felted mass composed of a granular and threadlike, basophilic inner portion and a well demarcated peripheral border. This peripheral border shows an inner basophilic zone and an outer deeply acidophilic zone which is characterized by the presence of clubbed mycelia. Diagnosis: Chronic inflammatory granulation tissue containing ray fungus compatible with actinomycosis" (fig. 2).

COMMENT

This patient had sulfanilamide, wet dressings, elevation of the left arm and bed rest, which controlled the acute cellulitis that immediately followed the human bite. But he was never given adequate drainage of the infected bite wound area until two and a half years after the chronic infection began. The tissues at the site of the bite wound were almost certainly devitalized by a strong chemical antiseptic immediately after the bite, and there was an acute purulent infection two to five days later. The measures used to control the cellulitis did not control the actinomycotic infection of the injured tissues.

The difficulty in culturing the pathogenic actinomycetes is well known, and our unsuccessful attempt to culture them from the pus is therefore not surprising and does not contradict the diagnosis.³ In this case the diagnosis of actinomycosis was made in the absence of other causative agents on the basis of the history and on the finding of the typical sulfur granules in the granulation tissue.

Cope and McWilliams each reported one case of actinomycosis following a human bite. Cope's case was similar to the one reported here.³ Following a human bite of the hand in the soft tissues between the first and second metacarpals, the patient developed a cellulitis which subsided on rest and elevation of the part. Subsequently a chronic inflammation developed in the area, repeatedly suppurating until after several months the lesion was adequately drained and the granulation tissue cleaned out. Actinomycotic granules were found in the granulation tissue. The lesion healed promptly and permanently after the adequate drainage.

In McWilliams' case the actinomycosis started slowly, after a tooth wound of a finger.⁴ This infection caused sclerotic and cystic changes in the underlying bone, and the chronic suppuration of the soft tissues discharged through several sinuses. At surgical exploration of this lesion the diagnosis of sarcoma led to amputation of the finger. Postoperative examination of the soft tissues revealed sulfur granules typical of actinomycosis. The bone changes were apparently secondary to the pathologic changes in the soft tissue, for no actinomycetes were found in the bone. No extension of the lesion subsequently occurred.

The actinomycetes are a large and important group of microorganisms that have a very labile morphology.⁵ The types that concern the agriculturist are aerobic, while most students of

actinomycosis have concluded that the anaerobic or microaerophilic *Actinomyces bovis* of the Wolff-Israel type is the usual human pathogen.⁶

The fundamental growth pattern of the actinomycetes is that of a fungus in which there is an axial filament with true branching. This pattern, under certain environments such as the human mouth, may be modified to a fragmented or bacillary form, as noted by Henrici and others.⁷

Pathogenic actinomycetes are most often recognized in tissue when their branching mycelia form typical clumps, or sulfur granules. In such characteristic colonies the mycelia have developed hyaline caps on their peripheral tips, and these caps or clubs give the sulfur granule its characteristic appearance.

The diagnosis of actinomycosis must not be made on the basis of sulfur granules alone, because other organisms, such as *Actinobacillus*, can form them too. However, if these sulfur granules, having been crushed, stained and studied microscopically, show basophilic axial filaments with true branching, actinomycosis is the logical diagnosis. Cope stated that from the clinician's point of view "both for diagnosis by smear and for cultural purposes it has proved necessary to isolate the actual sulfur granules from the pus and granulation tissue. Seldom were separate mycelial filaments found in the pus or was a growth of the organism obtained from random samples of pus."⁸

There are two general theories of the mechanism of human actinomycotic infection. The first is the exogenous theory. According to this one the ray fungus is conveyed to man from vegetable sources such as grasses and soil. It is true that actinomycetes are very plentiful in alkaline soil, but a convincing argument against this theory is the fact that actinomycetes found in soil and on grain are predominantly aerobic, while the human and animal pathogen is microaerophilic.¹ Furthermore, typical actinomycosis has not been produced in laboratory animals by aerobic actinomycetes obtained from vegetable sources.⁹

The second, or endogenous, theory of actinomycotic infection does not attempt to explain from what source *Actinomyces bovis* is originally conveyed to the human body but suggests that it is a normal inhabitant of the mouth and digestive tract.¹⁰ Crowley suggested that "they fill a role analogous to the organisms of Vincent's infection, which are present in the mouth without necessarily causing infection."¹¹ Sullivan and Goldsworthy think that "they lead a saprophytic existence in the mouth and invade the tissue only when conditions are rendered favorable, as by injury."¹²

Circumstantial clinical evidence which supports the endogenous theory is the coincidence of tooth extractions, particularly from pyorrhetic mouths, with the onset of cervicofacial actinomycosis.

The experimental support of this endogenous theory is recent work by Sullivan and Goldsworthy¹² and by Slack; also previous experiments by Lord, Naesland and others.⁹ Slack successfully reproduced actinomycosis in laboratory animals and concluded:¹³ "Anaerobic species of actinomycetes have been isolated from carious teeth, tonsils and pyorrhea pus and from the normal mouth. These organisms are not distinguishable morphologically from true agents of actinomycosis and they have similar cultural characteristics. . . . Progressive fatal experimental actinomycosis with sulfur granules was produced in 4 rabbits and 1 guinea pig inoculated with an anaerobic actinomycete isolated from pyorrhea pus."

SUMMARY

1. A case of actinomycosis secondary to a human bite was observed, and 2 similar cases were found in the literature.

13. Slack, J.: *Etiology and Pathogenesis of Actinomycosis*, J. Bact. 43: 193-209, 1942.

2. Actinomycetes indistinguishable from the known pathogenic *Actinomyces bovis* have been isolated from normal and diseased human mouths by several students of actinomycosis.

3. Experiments show that actinomycetes from the human mouth can cause true actinomycosis in animals.

4. It is logical to suspect actinomycosis in any persistent inflammatory lesion which stubbornly resists treatment, especially if it is at the site of a human bite wound.

5. It would seem from the few cases so far reported that with adequate surgical treatment the prognosis in cases of actinomycosis secondary to human bites is excellent.

CONCLUSION

A human bite can transmit pathogenic actinomycetes and cause actinomycosis.

A PROCEDURE TO CORRECT FACIAL PARALYSIS

EDWARD M. HANRAHAN, M.D., AND WALTER E. DANDY, M.D.
BALTIMORE

Herein are presented the results of a method of improving the appearance of the face after loss of the facial nerve. For many years the standard procedure for correcting facial paralysis

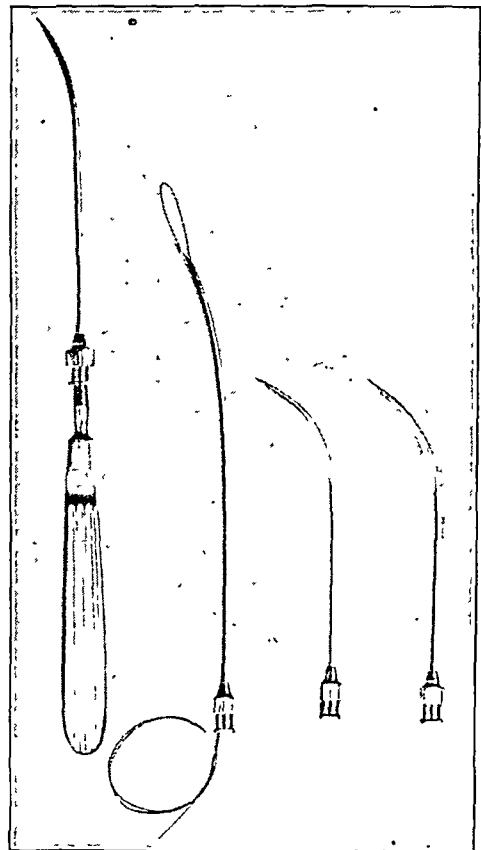

Fig. 1.—Assortment of hollow needles used for introduction of fascia. From left to right, a 12 cm. 11 gage (American standard wire gage) needle with removable handle. Second, a 14 cm. 10 gage needle showing wire loop used to grasp one end of a fascia strip. The two smaller needles, 10 cm., 13 gage, are used about the eye.

had been a spinofacial or hypoglossofacial anastomosis. The results were good but far from perfect. The advent of fascial strips slung from the temporal fascia to the lower and upper lips and to the lower eyelid produced results as good as if not better than the nerve anastomosis. However, each procedure left much to be desired. The nerve anastomosis never produced complete motor function in either the lower part of the face or the lower eyelid and, while in a certain percentage of cases there was automatic muscular control, in most instances the muscular activity was dependent on movement of the shoulder with spinofacial or of the tongue with hypoglossofacial anastomosis. On the other hand, with the fascial strips alone there was no motor activity and a complete absence of tone on the

affected side of the face. The procedure advocated here is a combination of the two procedures, i. e. the nerve anastomosis plus the fascial strips. The two are done at the same operation. The spinofacial anastomosis has been used exclusively. It is, of course, essential that the facial paralysis be of less than a year's duration; after that time return of motor function is not attainable. For paralysis existing over a year only the fascial

Fig. 2. Cerebellopontine angle acoustic tumor, right, removed Dec. 2, 1941. Spinofacial nerve anastomosis Dec. 13, 1941. A, appearance before fascial suspension on Nov. 28, 1942. The patient was able to move the muscles of the right side of the face by voluntary shoulder movements but there was scant relief of the paralysis at rest. B, condition eight days after fascial suspension.

strips are indicated. In a series of 17 cases so treated the facial paralysis resulted from the total removal of acoustic tumors in 7, from injury to the facial nerve during mastoid operations in 3, from the division of the facial nerve because of unbearable facial tic in three, and from a variety of injuries in 4.

The method of performing the spinofacial anastomosis needs no comment. It has long been a standardized procedure. We prefer the spinal accessory nerve to the hypoglossal because its loss is less obtrusive to the patient. Always one can be certain of return of motor power to the face because end to end anastomosis is made with intact nerves, i. e. without neuromas. The nerve suture is performed first because the field of operation is clean; immediately thereafter the fascial strips are implanted. In 17 cases only 4 were followed by any degree of wound reaction and in only 1 was there a frank infection. It is worthy of note that the latter case, treated with gramicidin, we consider to be one of our best cosmetic results.

The fascial strips were first introduced in this country for facial paralysis by Blair¹ and Brown,² who anchored them to the parotid fascia. Brown changed the anchorage to the temporal fascia and passed the strips into the temporal muscle, hoping for some resulting muscular activity. Although it is doubtful that this result is attained we have used this modification, feeling that at least the fixation to the temporal fascia is preferable. The fascial strips are carried across the midline of both the upper and the lower lips and looped through the sound muscle on the unaffected side. If the strips of fascia do not cross the midline they will not hold, and traction of the face will fail.

The temporal muscle flap with secondary attached fascial strips used by Gillies³ has been tried but with little if any

motor function resulting. However, it is not improbable that refinements of this method may yet bring better results.

Preliminary study of the face at rest and with the unaffected side in use will determine the most advantageous point on the paralyzed side at which to locate the nasolabial fold suspension. This point and the points on both upper and lower lips may be tattooed in the skin with a small hypodermic needle dipped in an alcoholic solution of brilliant green. These points will survive the most vigorous preoperative skin preparation and are of great value during the operation.

Anesthesia by intratracheal intubation through the nostril of the unaffected side supplies an airway and leaves the mouth clear for operative manipulation. Recently pentothal sodium has been used almost exclusively.

In obtaining fascia the Bateman stripper has been very satisfactory. It is essential that the longest possible strips be obtained to avoid splicing. It is probably preferable to anchor separately the two ends of the fascial loop from the upper and lower lips to the temporal fascia instead of carrying them through temporal muscle if this step requires a splice. Strips are cut about 1 cm. wide. Two or three may be obtained; they are cleared of any attached fat and split into smaller strips of about 5 mm. width; these are used for the suspension.

The temporal incision is only 5 or 6 cm. long and is placed within the hairline sufficiently posterior as to avoid any nerve fibers to the eyelids or frontalis; the incision ends at the zygoma.

The modified Reverdin needle devised by Blair is not always satisfactory. All too frequently its grasp of the end of the fascial strip is insufficient and necessitates repeated reintroductions with consequent trauma and possible contamination. A simple substitute is very effective. We have used large hollow needles 10 gage (American standard wire gage) and 14 cm. long, pointed and curved as shown in figure 1. To one end is attached a hub into which fits a removable handle. The handle facilitates its manipulation but is not necessary. This needle is introduced in the temporal incision, is pushed through the tissues of the cheek and emerges at one of the previously marked points, where a small stab wound is made. The handle is then removed and a loop of wire is inserted from above and appears through the needle point. One end of a fascial strip is placed in the wire loop, which is drawn backward until the fascia is tightly engaged against the needle opening. By strongly pulling the wire bearing one end of the strip, the needle

Fig. 3.—Appearance six months after the combined operation performed for facial tic. A, the face at rest. B, the facial response on voluntary movement of the shoulder.

and fascia are drawn into the temporal incision. The needle is then reintroduced in a parallel course and emerges at the same point, where it grasps the other end of the same strip and in so doing creates a loop of fascia around the orbital muscles of the sound side. Each of the stab wounds in the lips is closed by a single suture. Each end of the strip is now inserted deeply into and out of the temporal fascia and muscle by a Gallie needle, about 1 cm. apart, and tied. The knot is rein-

2. Brown, J. B.: The Utilization of the Temporal Muscle and Fascia in Facial Paralysis, Ann. Surg. 109:1016, 1939.

3. Gillies, H.: Experiences with Fascia Lata Grafts in the Operative Treatment of Facial Paralysis, Proc. Roy. Soc. Med. 27:1372, 1934.

forced with a silk suture and the ends are tacked down to the temporal fascia. The temporal attachment may be deferred until the strips have been similarly introduced to the remaining two points. Corresponding fascial ends should be clamped together for identification. The deformity must be appreciably overcorrected, almost to the limit to which the movable tissue can be suspended. The overcorrection has usually adjusted itself by the time the patient is ready to leave the hospital on the tenth day. The excess skin seen in long standing cases should be removed from in front of the ear.

The passage of the needle through the cheek is facilitated by guidance with the fingers of the left hand within the mouth. The use of gauze or preferably a cotton glove on this hand, at this stage, permits better control and avoids perforating the mouth with the needle. Rubber gloves are changed when the intraoral steps have been completed.

The passage of the needle should be midway between skin and mucosa. If too near skin, ridging and puckering result. If too near the buccal mucosa, the fascia may subsequently erode through from pressure against the teeth. The uppermost strip of the loop to the lower lip should be near the vermilion border; a deeper position causes eversion of the lower lip. The position of the parotid duct must be remembered.

Frequently a 3 mm. tarsorrhaphy at the outer canthus will be sufficient correction for a mild paralytic ectropion. If this condition is more severe the Kuhnt-Szymanowski operation or a fascial suspension of the lower lid, attached to the frontalis fascia as described by Blair, is preferable. The latter is done with a smaller hollow needle and wire loop, as described. A tendency toward a bowstring effect at the inner canthus is lessened by insertion of the fascia twice through the periosteum of the nasal plate by a Gallie needle.

The face is supported by a pressure bandage for a week and thereafter by collodion-gauze strips. Liquid diet and restricted talking are indicated for a week. We have given sulfadiazine by mouth in most cases for about five days, or until we are certain of clean wound healing. Similar precautions against infection are used before operation.

STAPHYLOCOCCUS ALBUS OSTEOMYELITIS AND SEPTICEMIA TREATED WITH PENICILLIN

O. CHARLES ERICKSEN, M.D., SIOUX FALLS, S. D.

This article describes the successful employment of the sodium salt of penicillin in a case of *Staphylococcus albus* osteomyelitis and septicemia, with a description of the technic employed, and comments on the side reactions when the drug was given intravenously and intramuscularly.

REPORT OF CASE

History.—B. M., a white man aged 29, a farmer, was admitted to the McKennan Hospital, Sioux Falls, S. D., on Oct. 10, 1943 with the complaints of weakness, chills and fever and also pain in the right hip. The history of the present complaints was that about three weeks before he took ill with chills, fever and sudden severe pain in the right hip. This completely disabled the patient and he took to his bed. He was given sulfonamides by his local physician with no results. During these three weeks he had steadily lost ground, and he was so weak that he was hardly able to move around in bed and had lost approximately 20 pounds (9 Kg.); he also complained of pain in his muscles and bones and he had headaches.

The immediate past history was that he had contracted a sore throat and he thought he had the "flu." The more remote past history is of no consequence.

Physical Examination.—On entry to the hospital and when first seen by me, the patient appeared acutely ill, toxic and extremely weak. The chief complaint then was pain in the right hip, weakness, chills and fever. The eyes, ears, nose and throat and the heart and lungs were normal. The blood pressure was 110 systolic, 70 diastolic. The pulse ranged from 80 to 110 and the temperature from 101 to 103 F. for the first thirteen days. There was no evidence of cutaneous or subcutaneous lesions at this time. There was no generalized adenopathy.

The liver was not palpable. The spleen was palpable and somewhat enlarged. The patient was emaciated.

The right leg was flexed at the knee and in abduction and was extremely tender on palpation and on pressure over the upper third of the femur.

The urine was normal. Examination of the blood revealed hemoglobin 72 per cent, red blood count 4,160,000 and leukocytes 6,400, with polymorphonuclears 58 per cent. Several blood cultures were made which revealed a growth of *Staphylococcus albus* in great profusion. No other organisms were ever found in the blood cultures.

X-ray examination revealed a definite area of bone necrosis in the upper third of the right femur.

Clinical Course.—The patient was first given large doses of sulfadiazine, which did not seem to benefit him at all. This medication was continued for four days and then it was changed to sulfathiazole, which was continued up to November 4 without any apparent benefit. On November 1 the patient was given a blood transfusion, which did not seem to do him any good except to pep him up somewhat. Blood cultures were positive for *Staphylococcus albus* throughout this entire period. All this time he complained of pain in his bones, hips, chest and ribs, and he was hardly able to cat. He was extremely depressed. He was losing ground rapidly.

On November 1 it was noticed that on both legs, the abdomen and the arms there had developed approximately 40 subcutaneous lesions about the size of a pea or a small lima bean. These were painful and bluish red. One of these lesions was opened and, although there was no pus present, on direct smears staphylococci were found, and cultures made of this lesion at the same time revealed a pure growth of *Staphylococcus albus*.

On the evening of November 4, seventeen days after his entrance to the hospital and thirty-eight days after the onset of the illness, 500,000 Oxford units of penicillin was obtained in the form of the sodium salt. He was given that same evening 49,000 units dissolved in 1,000 cc. of isotonic solution of sodium chloride. This was given over a period of seven hours by the intravenous drip method. The following day the temperature dropped to normal and the patient felt better. He stated that he had a feeling of well being and felt much improved; however, this might have been purely psychic, since he was told that this medicine would probably cure him.

This method of treatment of giving him 49,000 units of penicillin was followed for three days, and it was noticed that the subcutaneous lesions had disappeared within three days and the right femur felt much better; that is, there was no pain on pressure. However, following each injection the temperature would range from 102 to 106.4 F. orally, but the pulse rate would not exceed at any time 90 per minute. This drastic elevation of temperature was not preceded by a chill, and he did not feel at all ill through these periods of elevation of temperature, which lasted for about one-half hour or so and then would subside to 100 F. or below.

On the fourth day he was given the same dose of penicillin within twenty-four hours; it was divided into two doses every twelve hours. This method was continued for three days, and this was not followed by such severe reactions, since only once did the temperature rise to 104 F. and on other occasions rose only to 100, 100.6 and 101 F. It was thought that these febrile reactions were due entirely to the intravenous administration of the drug, so it was decided to give the penicillin intramuscularly every four to six hours in doses of 7,000 to 14,000 units. This was done for the next four days, when the supply of penicillin was exhausted. At no time after the intramuscular route had been decided on did he have any temperature above normal. On the other hand, the temperature from then on varied from 96.5 to 98.6 F., and the patient's condition was greatly improved. His appetite increased and he gained in weight. The subcutaneous lesions had entirely disappeared, and the tenderness in the right femur had disappeared. Blood cultures taken daily following the inception of the penicillin therapy at no time revealed any bacterial growth.

Dr. N. J. Nessa, roentgenologist, reported on November 10 that the right femur showed an apparent calcium deposit in the formerly reported osteolytic area.

On November 18 the patient was allowed out of bed and he walked, feeling well and desirous of going home. On November 19 he was dismissed, feeling well. He had but little complaint of pain in the right hip. He has been seen by me and checked over on three occasions since dismissal from the hospital. The last time was on Jan. 4, 1944, and he felt fine and wanted to go back to work. He had no complaint whatever.

COMMENT

This being the first case in which I have employed penicillin therapy, I feel that the results obtained, to say the least, were miraculous. The patient improved almost instantly and declared that he had a feeling of well being. The febrile reactions in this case, in all probability, were due to pyrogenic substances that were in the penicillin. When the penicillin was given intravenously, violent febrile reactions were obtained, but when it was given intramuscularly these febrile reactions did not occur.

ECONOMICS OF OBSTETRICS

J. D. LAUX

CORNING, N. Y.

At no time in medical history has the economics of obstetric care been of greater importance than at the present. Preserving maternal and infant life and decreasing maternal and infant mortality are vital to the continuation of our nation in the face of the destruction of life wrought by the war.

WHAT BARRIERS TO BETTER OBSTETRIC CARE?

Generally, the barriers to better obstetric care are pictured in glaring statistical terms of which the following are samples:

Nearly a quarter of a million women do not have the advantage of a physician's care at the time of delivery (Inter-Departmental Committee).

Fifty per cent of the mothers who die in childbirth in the United States die needlessly through ignorance, negligence or lack of adequate care (National Committee on Maternal Health).

Physicians estimate on the basis of experience that one half to two thirds of maternal deaths are preventable, that the still-birth rate can be reduced possibly by two-fifths and that deaths of newborn infants can be reduced at least by one third and probably by one half. This would mean a savings each year of more than 70,000 lives (Technical Committee on Medical Care).

Regardless of the strict accuracy of such claims, their purport has been driven home to the public.

A threefold attack on the problem of better obstetric care is usually recognized:

1. *Medical*.—Raising the quality of medical care through better training, postgraduate education and the discovery of new drugs.

2. *Educational*.—Education of prospective mothers, early selection of a competent physician and public cognizance of good medical legislation.

3. *Economic*.—Better economic status of patients, basically increasing incomes and improving housing, food and clothing as well as the means and method of procuring good care.

The problems in the medical and educational fields are cheerfully referred to those who are competent to deal with them. The problems in the economic field can only be sketched in outline in this paper.

COST OF OBSTETRIC CARE

What about the cost of obstetric care? One of the items on medical society fee tables from earliest times to the present has been the fee for normal delivery. In studies of medical society fee schedules by the Bureau of Medical Economics of the American Medical Association,¹ which I participated in, out of 384 schedules collected in 1934, 360 listed "normal delivery, one child" with the median average of \$25 for the service. Next to home and office visits, this obstetric fee was the most frequently listed item. Out of 539 schedules collected from 46 states in 1937 a total of 491 schedules gave the charge for "normal delivery, one child" with the median minimum fee again at \$25. Maximum fees for delivery were given by 105 schedules with the median at \$50. Clearly the prevailing charge for the basic obstetric service of normal delivery is around \$25.

Whether antepartum and postpartum services were also included in this prevailing fee was not clear, but generally the stated fee appeared to be for delivery only. However, in many cases the minimal fee was considered inclusive of complete antepartum and postpartum care. In fee schedules especially for welfare or indigent cases (established by medical societies in conjunction with county or state relief plans) confinement care is provided for fees of \$15 to \$25. Occasionally the services for such charges are limited to

Benefit Basis

	Medical Service Plan	Surgical Benefit Plan
Antepartum services:		
First visit (minimal physical).....	\$ 5	{ No benefit; services payable by patient
6 visits up to 7th month at \$2.....	12	
4 visits during 8th and 9th months at \$2	8	
Delivery:		
Delivery, including two weeks' after care	40	\$10
Postpartum services:		
2 visits, 4th to 6th week, at \$2.....	4	{ No benefit; services payable by patient
Additional services:		
10 urinalyses at \$1; 2 Wassermann or Kahn tests at \$1; differential blood count at \$2 and complete blood count at \$4; minimal charge of \$18	18	
Total benefit.....	\$87	\$10

delivery with three antepartum and postpartum visits. As charges for medical care of indigents are generally scheduled at 50 per cent of the prevailing charges, a fee of \$30 to \$50 was apparently considered appropriate for relatively complete obstetric care.

The determination of a charge for medical services such as home delivery is not subject to cost analysis. Custom, the chief factor in establishment of medical fees, is especially prominent in the fixing of fees for obstetric service. From midwifery (1750) to parturition (1836) to confinement (1900) to obstetric delivery (1930) the fee has been approximately the same.

EVALUATION UNDER MEDICAL SERVICE PLANS

The problem of reaching general agreement among physicians on the evaluation of medical service is particularly apparent in the development of prepayment medical service plans. The traditional "sliding scale" of fees, by which charges are varied according to the patient's ability to pay, has formed extremely heterogeneous ideas as to the proper charge for a service. Yet in actual practice there is a surprising uniformity of charges. Fees for usual services such as obstetric

delivery do not vary except in broad social-economic groups such as (1) indigent, (2) middle class, (3) wealthy. Persons in the middle class, which constitutes at least 70 per cent of the physician's clientele, are usually charged about the same fee, especially in urban areas where the income status of the patient is not well known by the physician. It is the impact of this changing relationship between physicians and patients that is bringing greater attention toward methods of prepaying or financing medical charges.

A review of schedules of payment for obstetric services under prepayment plans sponsored by medical societies indicates that a fee of about \$40 is established for the low income group, that is, those above the indigent subsistence level but below the comfort level of \$2,500 annual income per family. Persons enrolled whose income is above this limit are obligated to pay the physician's additional charge, if any. Likewise all antepartum and postpartum services are paid by the patient. In some few plans providing full medical services (antepartum and postpartum visit fees plus charges for urinalyses and blood studies in addition to the delivery) the payment amounts to at least \$87. The benefit basis for one such plan is given in the accompanying table. Providing benefits under the extended medical plan only for services actually rendered was believed an inducement to more complete obstetric service. Some plans limit the benefit for the complete confinement care to a flat amount such as \$50 without regard to the amount of service rendered.

WHY AN ECONOMIC PROBLEM?

On the surface it would appear that the relatively low fee of about \$25 for obstetric delivery would not cause any economic problem except for indigents. However, the depth of the problem is indicated by the fact that prepayment plans offering \$40 for delivery alone with the patient to pay for antepartum and postpartum services, or even the \$85 payable for complete care under medical plans, still cause general disquietude among physicians. Underlying is the question of differential fees for services of obstetricians as compared with general practitioners.

The level of fees charged by specialists in obstetrics is not generally recorded, but some evidence, from bills rendered patients under hospital and medical service plans, indicates that \$100 would be the prevailing charge to patients in the middle class group. There is no disputing that the services of an obstetrician for complete confinement care of patients in this group is properly valued at \$100 to \$150 in comparison with the minimal services so frequently rendered in general confinement care for charges of \$25 to \$50.

The problem is to assist more and more patients to obtain services such as rendered by obstetricians. Or, to state it more exactly, a place in the family budget should be made for more adequate obstetric care, thereby making possible the support of more fully trained obstetricians or more complete care from well trained general practitioners.

An interesting sidelight on the ability of patients to obtain the services of obstetricians is shown in a tabulation of the type of practitioner performing the first 1,220 deliveries under Michigan Medical Service, a prepayment plan sponsored by the Michigan State Medical Society. Of these deliveries only 12 per cent were performed by physicians limiting their practice to obstetrics. On the other hand, 84 per cent of the deliveries were performed by general practitioners.

Worthy of note is that the remaining 4 per cent of the deliveries were performed by specialists limiting their practice to a particular field other than obstetrics! Even when the bill is paid, patients obviously still wish to obtain services from physicians they know and in whom they have confidence rather than from practitioners who may have greater technical skill. Furthermore, there are too few obstetricians to care for more than a fraction of all deliveries. With less than 1 per cent of physicians, or a total of 1,700, limiting their practice to obstetrics and gynecology, it would be rather remarkable for them to take care of more than 12 per cent of the deliveries. With only one obstetrician-gynecologist for approximately 80,000 persons, each such specialist would have to perform about 1,600 deliveries annually to render all obstetric service. There is a larger group, constituting about 4 per cent of the total number of physicians, or some 6,800, devoting special attention to obstetrics and gynecology. However, it is apparent that the majority of normal deliveries will have to continue to be performed by general practitioners.

There are, of course, other expenses such as hospitalization, nursing and layettes which build up the economic problem of obstetrics. One study of what parents paid for 540 babies² reported an overall average cost of \$110, ranging from \$270 where parents are in comfortable circumstances (above \$3,000 annually) to \$129 for those earning \$1,200 to \$3,000 and \$64 for those less than \$1,200. The highest cost was \$692.

It is undoubtedly the fact that total expenses in connection with obstetric care run into three figures, which focuses emphasis on the charge by the physician.

Much attention has been given to alterations in the present system of distributing and paying for medical care. However helpful such proposals may be toward meeting the cost of actual medical care, no amount of change in the present system of medical practice will affect the really basic economic problem of sufficient income to make possible an adequate standard of living—food, housing and clothing as well as medical care. The direct approach of bolstering individual and family incomes is apparently too simple for social reformers. However, it must be granted that there are real impediments to overcome before all workers' incomes can be increased so they can afford a higher standard of living. Yet, the furor over socialization of medicine as a palliative means of improving the distribution of medical care should not be allowed to obscure the plain fact that the common living essentials such as food and housing and economic security are frequently more vital to good health than medical care. When experiments such as those in England show that improvements in the nutrition of expectant mothers reduced maternal mortality by almost one-half that existing among a control group of mothers not receiving additional food, the prospects of improving the distribution of such an essential should not be forgotten.

One aspect of maternal mortality where medical science is perhaps overshadowed by economics is that of maternal deaths due to abortion. It has been fairly authentically determined³ that 3,300 maternal deaths, 35 per cent of all maternal deaths, are due to abortion. The medical causes and possibly correctives of abortions have been extensively catalogued and analyzed. The

3. Dunn, Halbert L.: Vital Statistics—Special Reports (1941), United States Department of Commerce, Bureau of the Census, 1943, vol. 15, p. 431.

somewhat more basic economic factors such as poor nutrition, improper housing and overexertion in connection either with housework or with work in the office or factory cannot be as readily diagnosed or treated. These economic conditions perhaps in conjunction with a nervous-mental burden of unplanned pregnancies can overcome even the best obstetric care. Coupled with the fact that under such circumstances medical attention is too frequently delayed or not obtained, it is remarkable that the death rate because of abortion is not greater.

The medical profession is currently struggling with the question of child spacing. On the one side is a group of physicians who, perhaps because of religious belief or age, are unalterably opposed in their thinking to any condoning of artificial contraception. On the other side is a group of as equally distinguished physicians who urge dissemination of contraceptive information and devices. Because of moral implications, artificial contraception will probably always be a controversial subject. However, prominent physicians and church leaders have agreed that the natural rhythm method (Ogino-Knaus) of child spacing can be effectively utilized. Further substantiation of the scientific-medical basis of the rhythm method may be desirable, but it is believed that a simplified visual method of calculating rhythm periods is more acutely necessary before wide usage of this method will be possible. Undoubtedly the effect of child spacing on the underlying socioeconomic problems would help to overcome pregnancy wastage shown by the large number of stillbirths, neonatal deaths and abortions and would also help to reduce maternal mortality and morbidity.

With the large number of women now employed in war industries it is hoped that the economic factors of obstetric care will receive more proportionate attention. No really valid criticism can be maintained against the medical progress toward better obstetric care. Further progress awaits the development of the educational and economic factors connected with obstetric care.

MONEY VALUE OF HUMAN LIFE

A digression into the realm of so-called higher economics may be of interest. There has been considerable general speculation on the value of a human being. Usually these speculations end with the much quoted calculation that the chemical elements of the human body are valued at 69 cents. Most economists have hesitated to give any estimate of the money value of man. Some have taken the position that people are not to be counted as wealth because they are the reason for which wealth exists. Others incline to the position that human values should not be included in national wealth because the average lifetime consumption of a person approximately equals his production. A third class omits all approximations of human life values because of the difficulty of any accurate statistical measurement. However, there are economists who maintain that human life should be valued in cash to give a realistic picture of the total economic structure of a nation.

Placing a money value on human life is also desirable to give a commonly understood expression to the savings possible through conservation of life. Avoiding metaphysical or sentimental ideas, the economic value of an individual is measured by his earnings as a productive worker during his lifetime.

The only recognized economists who have attempted a cash estimate of human life have been Alfred Marshall

and Irving Fisher. Marshall's estimate of \$2,700 applied to Englishmen in 1895. Fisher's estimate of \$10,000 for Americans was made in 1910. In the insurance field the value of life is closely related to the present worth of future earning. On this basis, Dublin and Lotka⁴ estimated the value of a child at birth from \$3,000 to \$16,050, depending on the income class of maximum earnings. There are other money values placed on human life, such as prices paid for slaves ranging from \$21 to \$2,000 and court awards for death damages ranging from \$1,500 to \$70,000.

Using the discounted value of net future earnings (that is after deducting the expenses of raising a child) for the median income of \$2,000 annually, it is fairly accurately estimated that the value of a child at birth is \$9,000 and at 21 years of age \$30,000.

Relating these valuations of human life to obstetric fees, it can be seen that the charge for delivery is only $\frac{1}{3}$ to $\frac{1}{2}$ of 1 per cent of the value of the child at birth. In relation to the value of the lives of both the mother and child, the obstetric charge is only $\frac{1}{10}$ of 1 per cent. The tremendous importance of decreasing maternal mortality purely from the economic point of view is evidenced by the fact that each year about \$250,000,000 is the value of maternal lives lost. Likewise the savings possible through decreasing infant mortality could amount to \$1,600,000,000. The assets of the United States are too commonly measured in terms of factories, lands and minerals. The greatest assets are the men, women and children. In fact, human beings are to be valued in terms of productive capacity at five times the value of all the material assets of the nation—including the recent valuation made by Mr. Ickes.

All this indicates the key position that good medical care and especially good obstetric care plays in the economic status of the nation.

GOVERNMENT PROGRAMS

Increased attention to medical service, especially maternal care, as a field for organized action on the part of government agencies is apparent. The acceleration toward more government participation in payment of medical services began with the appropriation of \$22,200,000 for Health and Welfare Service under the Social Security Act, of which \$5,820,000 was specifically for maternal and child health. In a sense, the old Shephard-Towner Act of 1921 bringing the use of federal funds into the field of maternity and infancy was renewed—after a two year revival—in 1927. This time the allotment of federal funds for maternal and child care was firmly entrenched under the supervision and control of the Children's Bureau.

Total government expenditure for health, including state and federal funds, is placed at \$706,900,000 for 1941 by the Social Security Board,⁵ which amount is 11 per cent of the total Social Security and related programs. However, this is an understatement of government outlay for health, since expenditures for medical care incidental to other programs such as those in connection with Army, Navy, Education and Farm Security Administration are not included. Of this huge governmental medical financing, \$9,300,000 is especially allocated for maternal and child health services.

With the policy of grants-in-aid established, there is little likelihood that state legislatures will abandon use of federal funds available when combined with state

4. Dublin, L. I., and Lotka, A. J.: *Money Value of a Man*, New York, Ronald Press, 1930.

5. *Social Security Year Book*, Federal Security Agency, Social Security Board, 1941, p. 37.

funds. Under such a pattern for distributing payments for medical services, it seems that the medical profession would be well advised to devote attention to professionally sponsored agencies for administering these medical funds. This is almost as important for the good of the patient as the scientific methods of diagnosis and treatment.

It is of particular significance that the most recent extension of government payment for medical care was to pay for the obstetric-pediatric care of wives and children of servicemen in the fourth (\$78 per month) to the seventh grades (\$50 per month). An appropriation of \$4,400,000 for this purpose has been granted to the Children's Bureau for the fiscal year ending June 30, 1944. Another appropriation bill, H. R. 2041, is designed to continue this obstetric-pediatric program for the duration and six months after the war with an annual appropriation of \$6,000,000. However, the plan of paying for obstetric care of the wives of servicemen was quietly started under the Maternal and Child Health program of the Children's Bureau on request from state health agencies. From August 1942 to February 1943 over \$390,000 was expended for this purpose. Already forty-three states and territories have programs approved by the Children's Bureau under the new separately financed program. Between March 1943, when this program started, and August 1943, 29,910 soldiers' wives had received "free maternity care." Payments, which are generally administered through state health departments, provide \$25 for delivery, \$10 for antepartum care and laboratory, and \$5 for postpartum care and laboratory, or \$40 for confinement. A like sum of \$40 is payable for hospitalization. Approximately 5 per cent of all births, or at least 70,000 annually, are expected by the Children's Bureau to be cared for under the program.

In several states the medical profession has pointed out that payments for this purpose should be added to the servicemen's family allotment, thereby eliminating the need for a new fund distributing agency of the government. Another concern of the medical profession is to keep the determination of the amount of fee for the service an individual matter between the patient and the physician. Hence the request that payments be made to servicemen's wives as supplemental funds. However, the payment is allowable only on receipt of obstetric-pediatric care, and the Children's Bureau apparently considers the wives of all servicemen below the rank of a commissioned officer eligible for the care with the entire payment to be made from government funds at the stipulated fee.

Here again is need for a professionally sponsored agency to handle the administration of funds for medical care. Note in particular that plans for this program were to be developed and administered by state health agencies. Fortunately there is some tendency for even federal government proposals to take the shape of furnishing necessary funds with the distribution of payments and arrangements for medical services by voluntary nonprofit agencies. For example, the Farm Security Administration has so financed 1,044 medical care programs which provide service, including obstetric care, for 613,054 persons through voluntary and usually medical sponsored and administered agencies. Likewise the National Resources Planning Board proposals for extension of Social Security stress financial aid to states through cooperation with the medical profession

in plans to help patients pay medical expenses on a budget prepayment basis. This program has been translated into proposed legislation by the Wagner-Murray-Dingle Social Security Bill (S. 1161 and H. R. 2861), which grants the Surgeon General authority to negotiate both the method of payment and the fees with private agencies.

There is no question about the magnitude of the decision facing the medical profession on the economic front. Two courses are open: (1) to oppose use of government funds in medical care except for care of the indigent sick; (2) to accept use of government funds in medical care for those above the indigent level provided the medical profession has full voice in decisions concerning the distribution of such funds.

From the economics of the problem, it is my conclusion that such funds should be used under sound plans sponsored by the medical profession.

VOLUNTARY PROGRAMS

The turning of government from the provision of actual medical service to programs whereby the funds are furnished by government with the distribution of payments and arrangements for service made by private agencies is primarily due to the growing success of voluntary nonprofit prepayment plans. Such plans organized on a state or regional basis, under sponsorship of the medical profession, permit payments to all qualified physicians and endeavor to let the subscriber receive medical service in essentially the same manner as prior to organization of the prepayment plan.

There are thirty-three such plans in operation in fifteen states providing services for more than 750,000 persons. Similar plans are being proposed in twenty-one areas in sixteen other states. Likewise there is a plan in Hawaii (it survived Pearl Harbor) and four in Canada. A Medical Service Plans Council for these plans has been formed to coordinate and stimulate an exchange of administrative and statistical experiences.

Continued expansion of voluntary plans, both hospital service and medical service, is becoming of ever greater significance to the private practice of medicine—especially obstetric practice. Conversely, the importance of obstetrics to prepayment plans is indicated by the statement of an actuary of a large hospital service plan that "maternity utilization is the best single index of the financial condition of a hospital service plan." The same is also true for medical and surgical service plans. Under such plans, maternity cases (including complications of pregnancy, childbirth and the puerperium as well as deliveries) rank first in number and in cost.

Most medical service plans have striven to lift the quality and quantity of obstetric care by providing a fee which would encourage more adequate care from general practitioners and yet fairly recompense the obstetrician for his services. Even under the limited surgical plans the delivery fee of \$40 assures the general practitioner more than the average for complete care. This, with the opportunity for some additional payment by the patient for antepartum and postpartum care, should give an impetus for even more adequate care. Likewise the \$40 delivery fee does not prevent the obstetrician from receiving proper recompense of \$100 to \$150 for his extensive care.

Some plans specifically provide a higher fee for physicians who limit their service to obstetrics but may

provide that the patient must be referred by a general practitioner before the case can be considered as warranting a specialist fee. An accompanying provision is that no payment will be made to a specialist for services outside his field of specialization. Where these or similar arrangements under medical society sponsored plans are formulated by committees of physicians thoroughly familiar with the professional problems involved, it is surprising the amount of heat that is generated by practical application under a functioning plan. Nevertheless, medical societies should be able to develop a workable plan which will win the support of the majority of physicians.

The obstetric-gynecologic experiences under the Surgical Benefit plan of Michigan Medical Service gives an interesting picture of the possibilities of prepayment. For an average cost of 61 cents a month per person (60 cents for single subscriber, \$1.60 for two persons and \$2.25 for family including all children up to 18 years) the subscribers are entitled to practically unlimited surgical and obstetric procedures for hospitalized conditions. Participating physicians render these services without additional charge beyond the payment by the plan if the subscriber's family income is less than \$2,500 annually. Subscribers with greater incomes are obligated to pay the physician the difference, if any, between his usual charge and the payment from the plan. The benefits paid by the plan are fully equivalent to the prevailing charge for the service. As examples: delivery, \$40; cesarean section, \$100; ectopic pregnancy, \$125; perineorrhaphy, \$50; rectovaginal fistula, \$100; dilation and curettage, \$25; hysterectomy, vaginal \$125, abdominal \$150; oophorectomy, \$100; ovariectomy, \$75, and salpingectomy, \$100.

On the basis of several years of operation representing over 3,500,000 member months of experience, the following points seem to be confirmed:

Obstetric services (including normal delivery, cesarean section, ectopic pregnancies and miscarriages) are required by 20 per cent of the patients and represent 19 per cent of total payments.

Normal deliveries at 24 per thousand subscribers annually is about $1\frac{1}{3}$ times that for the general population.

Average obstetric payment is \$42.50 including, besides the \$40 payment for normal delivery, payments for cesarean and ectopic operations.

Frequency of obstetric and gynecologic operations is in the following order: 1. Suspensions. 2. Hysterectomies. 3. Salpingectomies. 4. Dilations and curettages. 5. Deliveries (including normal, cesarean, ectopic and miscarriages). 6. Oophorectomies. 7. Ovariectomies.

Gynecologic operations (female, abdominal and pelvic) are required by 12 per cent of all patients and represent 22 per cent of total payments.

Gynecologic specialists cared for 3 per cent of all patients and received 5 per cent of total payments.

The average gynecologic payment is \$100.

Of the 61 cents per month paid by each subscriber, 52 cents is paid to the physician for services and 8 cents is used for administration, leaving 1 cent for reserves.

Obstetric and gynecologic services together represent 41 per cent of the total cost of all services (12 cents a month per person for gynecologic and 10 cents a month per person for obstetric services).

In Mr. Churchill's words, "the magic of the averages to the rescue of the millions" is shown by the fact that 10 cents a month per person will pay for all obstetric deliveries at fair fees (as has been indicated) and that

12 cents a month per person will also provide fair fees for all gynecologic corrective and restorative operations. Including administration expenses, the total cost of 30 cents a month per person, or about \$15.35 a year per family, would afford full access for every family to the benefits of essential and greatly needed obstetric and gynecologic surgery services.

It remains for the medical profession to formulate workable programs embodying the prepayment principle.

SUMMARY

The barriers to better obstetric care are more largely economic and educational than medical.

Physicians' charges for the obstetric service of normal delivery are generally nominal amounts of \$25 to \$50. Yet, in connection with the expenses of specialists' services, hospitalization and nursing, an economic problem does exist in obstetric care. The problem is to find a place in the family budget for the support of more fully trained obstetricians or more complete care from well trained general practitioners.

A monetary valuation of a newborn child at \$9,000 and of an adult at \$30,000 indicates a loss due to maternal and infant deaths of close to \$1,850,000,000 annually—demonstrating the importance of good obstetric care in the economic status of the nation.

Government participation in payment for medical services, particularly for obstetric care, is definitely increasing. The medical profession is facing the decision of either opposing use of government funds except for the indigent sick or accepting government funds, provided the profession has full voice in the decisions concerning arrangements for distributing such funds. The economics of the problem point toward utilization of government funds under sound programs advanced by the medical profession.

Voluntary, nonprofit, prepayment medical plans are becoming of ever greater significance to the private practice of medicine—especially obstetric practice. The prospects for obstetric-gynecologic practice under prepayment is shown on the basis of experiences with the Michigan Medical Service plan, where \$15.35 a year per family provides extensive obstetric-gynecologic surgery and fair fees for the physicians.

No amount of change in the present system of distribution and payment for medical service will affect the basic economic problem of sufficient income for every worker to make possible a higher standard of living—food, clothing and housing as well as medical care.

65 East First Street.

Food Requirements.—Food requirements vary with age, sex, weight and surface area, the last being perhaps of greatest importance. Since the determination of surface area is somewhat difficult it is usually believed to be sufficiently accurate to employ the standard tables of caloric requirements per kilogram of body weight in computing the total diet needs. These requirements are, roughly, at rest, 25 to 30 calories per kilogram ($2\frac{1}{2}$ pounds); at light work, 35 to 40 calories per kilogram; at moderate work, 40 to 45 calories per kilogram; at hard work, 45 to 60 calories per kilogram. Most food requirement tables state that children from 6 to 16 need approximately 50 to 90 per cent of the food needed by an adult male at moderate activity.—*The Hospital in Modern Society*, edited by Arthur C. Bachmeyer and Gerhard Hartman, New York, Commonwealth Fund, 1943.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS. HOWARD A. CARTER, Secretary.

SATURATED AIR FEVER THERAPY UNITS ACCEPTABLE

Manufacturer: Equipment Service Company, 915 Behan Street, Pittsburgh.

The Saturated Air Fever Therapy Units are designed to produce temperature rises either in the whole body by general application or in the arms, legs or back by local applications. The units are of three types: the one for general application accommodating the entire body except the head, and two types for local applications, the one for treating the torso and the other for treating the extremities.

The fever therapy box contains an air conditioning system of the general dew point type in which a highly atomized water spray in the upper end of a small duct supplies both the motive power for circulating air and the heat and moisture for saturating it at the desired temperature.

A water temperature of 130 F. will produce a uniform saturated atmosphere of from 120 to 125 F. Since the air is saturated on entering the box, and loses heat before being returned to the air conditioning part of the cycle, saturation is insured throughout.

The unit was examined by the Council, and it was found to be a practical apparatus for administering fever therapy. The comfort, safety and quality of the heat given by this source of saturated moist air was found satisfactory.

The Council on Physical Therapy voted to accept the Saturated Air Fever Therapy Units for inclusion in its list of accepted devices.

BELTONE HEARING AID, MODEL 603H, ACCEPTABLE

Manufacturer: Beltone Hearing Aid Company, 847 West Jackson Boulevard, Chicago.

The Beltone Hearing Aid, Model 603H, is a vacuum tube instrument consisting of a transmitter with a crystal microphone and a large crystal receiver, and a battery unit. The device was examined by the Council and the results of that examination are as follows:

Beltone Hearing Aid
Model 603H.

Weights and overall dimensions of the various parts. transmitter, $3\frac{3}{4}$ inches by $2\frac{1}{4}$ inches by $\frac{3}{4}$ inch; weight with cords and receiver, 6 ounces. Crystal receiver, 1 inch in diameter. Batteries weigh 11 ounces. The total weight of the entire instrument is 17 ounces.

Batteries.—Voltages and current drains are as follows:

A-battery, 1.5 volts; current drain at $\frac{1}{2}$, $\frac{3}{4}$ and full volume, 82 milliamperes. B-battery, 45 volts, current drain at $\frac{1}{2}$, $\frac{3}{4}$ and full volume, 1.0 milliampere. The set may be used with a 1.5 volt A-battery and a $22\frac{1}{2}$, 33 or 45 volt

B-battery. All tests were made with the 45 volt battery.

All required data have been furnished by the manufacturer, such as description, amplification graphs, guaranty certificate, instructions for use and list of servicing agencies. The service plan as described is satisfactory.

Acoustical Gain.—(Average of observations of two trained observers using fitted ear molds seated 5 feet from loud speaker delivering frequencies of pure sine wave characteristics.)

Volume Control				Frequency			
Set at	256	512	1,024	1,448	2,048	2,896	4,096
$\frac{1}{2}$	3	12	12	16	15	9	7
$\frac{3}{4}$	7	17	17	18	20	18	24

Physical and Mechanical Features.—The instrument consists of a black molded plastic case of pleasing appearance and is apparently sturdily built. A single control consisting of a plastic disk 1 inch in diameter and $\frac{3}{16}$ inch thick serves both as the off and on switch and the volume control. No attempt is made to modify the frequency response.

Performance.—In general the performance of the instrument is good and quite as represented. There is a minimum of internal noise and practically no feedback squeal. At maximum intensity some distortion develops, but for any practical purpose this maximum intensity would not be necessary.

The Council on Physical Therapy voted to declare the Beltone Hearing Aid acceptable for inclusion in its list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

AUSTIN E. SMITH, M.D., Secretary.

DIPHTHERIA TOXOID, TETANUS TOXOID, ALUM PRECIPITATED, COMBINED (See New and Nonofficial Remedies, 1943, p. 549).

The following additional products have been accepted:

GILLILAND LABORATORIES, INC., MARIETTA, PA.

Combined Diphtheria-Tetanus Toxoid, Alum Precipitated: 1 cc. and 10 cc. vials in packages of two 1 cc. vials and of one 10 cc. vial.

LEDERLE LABORATORIES, INC., PEARL RIVER, N. Y.

Refined Diphtheria-Tetanus Toxoid, Alum Precipitated: 1 cc. and 10 cc. vials in packages of two 1 cc. vials and of one 10 cc. vial.

PARKE, DAVIS & Co., DETROIT

Diphtheria-Tetanus Toxoid (Combined): Packages of three 2 cc. vials and packages of one 30 cc. vial.

SHARP & DOHME, INC., PHILADELPHIA

Combined Diphtheria-Tetanus Toxoid, Alum Precipitated: 1 cc. and 10 cc. vials in packages of two 1 cc. vials and of one 10 cc. vial.

ESTROGENIC SUBSTANCES (See New and Nonofficial Remedies, 1943, p. 401).

The following dosage forms have been accepted:

CHEPLIN BIOLOGICAL LABORATORIES, INC., SYRACUSE, N. Y.

Ampule Solution of Estrogenic Substance (in oil): 1 cc. size containing the equivalent of 2,000 international units per cubic centimeter, 5,000 international units per cubic centimeter, 10,000 international units per cubic centimeter or 20,000 international units per cubic centimeter of estrone in sesame oil with benzyl alcohol 3 per cent.

TUBERCULINS (See New and Nonofficial Remedies, 1943, p. 565).

The following dosage form has been accepted:

PITMAN-MOORE COMPANY, INDIANAPOLIS

Tuberculin (Diagnostic): Packages containing three 1 cc. diaphragm stoppered vials of tuberculin, one of each dilution 1:100, 1:1,000 and 1:10,000. Preserved with 0.5 per cent phenol.

MENADIONE (See New and Nonofficial Remedies, 1943, p. 619).

The following dosage forms have been accepted:

JOHN WYETH & BROTHER, DIVISION WYETH INCORPORATED, PHILADELPHIA

Ampul Menadione (in corn oil) 1 mg. per cc.: 2 cc.

Tablets Menadione: 1 mg.

AMYTAL (See New and Nonofficial Remedies, 1943, p. 481).

The following dosage form has been accepted:

ELI LILLY AND COMPANY, INDIANAPOLIS

Tablets Amytal: 32 mg.

SATURDAY, APRIL 8, 1944

CONFUSION CONCERNING SHOCK

The term shock has been loosely applied to a number of apparently unrelated conditions. Many regard it as a state of acute circulatory failure characterized by prostration, apathy or stupor, tachycardia, feeble regular pulse and diminished blood pressure. The effects of syncope, fright, exhaustion, anesthesia, hemorrhage, primary shock, cardiac failure or secondary shock conform to this broad application of the term.

The attention of surgeons is focused on shock following trauma. Some of them recognize¹ that at least three mechanisms may cause low blood pressure after injury. One of these, primary or neurogenic shock, is a neurovascular reaction like that of syncope or fainting. This develops promptly after injury and is usually transient unless accompanied by extensive trauma or hemorrhage. Occasionally primary shock may merge gradually into secondary shock without an interval of partial recovery. Recent experiments² indicate that hemoconcentration is not present in primary or neurogenic shock.

Low blood pressure may develop promptly from voluminous hemorrhage or gradually from slow or repeated small hemorrhages. The clinical signs of hemorrhage are like those of secondary shock, but it has been shown³ that they differ in other important particulars. Hemorrhage is followed by rapid dilution of the blood which, in otherwise normal subjects, is proportional to the volume of blood lost. Low blood pressure occurring shortly after trauma is due chiefly to neurogenic and hemorrhagic effects.

The third mechanism results from deranged capillary function. Products of tissue autolysis or of infection, absorbed from damaged tissues, produce systemic effects like those of capillary poisons. Consequent leakage of

fluid from the blood into the tissue spaces disturbs fluid balance, lowers the blood volume and causes hemoconcentration. Decreased blood volume, combined with an increased volume capacity of the capillary bed, causes circulatory deficiency. This mechanism requires time for development; it is never seen immediately after injury and hence is called delayed or secondary shock.

Recent reports both by English and by American authors indicate confusion in attempting to analyze the causes of low arterial pressure after traumatic injuries. Data were collected on hemoconcentration, blood volume, blood pressure and other clinical features, but these items showed little uniformity. The injuries described varied widely in character, in severity, in amount of blood lost and in other features. Obviously it is difficult to correlate such various items into a logical picture.

A few causes for bewilderment are apparent and should be eliminated. Cases of traumatic injury present varying combinations of neurogenic shock, hemorrhage and secondary shock, each characterized by low arterial pressure. The importance of these items varies from case to case, and a formula has not yet been devised by which their relative weight in such a combination may be evaluated.

Circulatory deficiency following trauma may be due to neurogenic reactions, to the effects of hemorrhages, to absorption of toxic products or may be due in part to each. Traumatic shock is not a disease entity but a syndrome; it represents the summative effects of several factors. These vary in different cases and in the same case at different times. Obviously the mechanisms involved in shock from trauma should be studied separately as neurogenic, hemorrhagic, toxic and perhaps other factors.

Continued efforts to explain traumatic shock on the basis of a single mechanism prolong the confusion. The recognition of several contributory causes, including toxic factors, will go far toward establishing agreement. Investigations on other features of shock may then go forward in an atmosphere somewhat cleared of controversial discussions.

The basic principles on which agreement seems possible are as follows: Surgical shock, like that resulting from extensive trauma, is not due to a single cause but to a combination of causes: the anesthetic, the local loss of blood and fluid, emotional and neurogenic reactions, infection or intoxication which may have reduced the patient's physiologic state, the disease itself which necessitated operation, and toxic products of autolysis or of infection absorbed from traumatized tissues. The relative importance of these factors varies in different cases and they operate in varying combinations. Some of these factors are lacking in shock from other causes.

The occurrence of secondary shock is not limited to traumatic injuries, burns and the aftermath of extensive surgery. Similar circulatory deficiency may develop incident to abdominal emergencies, severe infections,

intoxications such as icterus gravis or eclampsia, and from the effects of anoxia and of various poisons. In such instances, neurogenic shock and the effects of hemorrhage usually are not present; toxic factors are of major importance, and the mechanism is probably that of capillary relaxation and endothelial permeability.

CLINICAL THERMOMETRY

How long does it take a clinical thermometer to record body temperature accurately? The answer apparently is not known by all those who use this instrument of precision, according to DeNosaquo, Kerlan, Knudsen and Klumpp.¹ In order to learn what schools of nursing are teaching with respect to taking temperatures, a questionnaire was sent to one hundred outstanding schools. According to the replies, twenty-seven schools taught their students that the time required for accurate registration was less than three minutes, thirty-seven stated three minutes and only five recommended an interval longer than three minutes. Many clinical thermometers on the market bear such designations as "½ minute," "1 minute" or "60 seconds," which obviously suggests to the user that the time required to register body temperature is that inscribed on the instrument.

The authors conducted a clinical and physical study to determine, first, how long it takes instruments of various makes and types to record body temperature and, second, whether or not there is any consistent difference between instruments bearing different time designations. On the basis of a series of observations, the validity of which was statistically controlled, the authors concluded that an insertion time of three minutes should be the minimum interval for oral clinical thermometers under ordinary conditions of use. It was also found by them that variations in the configuration of the bulb made no appreciable difference in the time required to reach the final reading. Similarly the time stamped on the thermometer did not have any relation to the length of time required by the instrument to reach equilibrium, and in all circumstances a longer time was needed to give an accurate reading than that imprinted on the thermometer to give an accurate reading.

In view of these observations it would seem to be a good thing for thermometer manufacturers to eliminate from their instruments time designations, which can only be misleading and result in serious diagnostic and therapeutic misimpressions.

There is no instrument of precision that is more valuable in the diagnosis and prognosis of disease than the clinical thermometer. It is therefore essential that it be given sufficient time to record accurate information. There is a temptation these days to rush everything; but when it comes to taking temperatures it is the course of wisdom to make haste slowly.

PRIORITY IN THE DISCOVERY OF FEVER THERAPY IN PSYCHOSIS

Priority for the use of malaria and relapsing fever in the treatment of dementia paralytica, according to Neymann,¹ should belong to Rosenblum. In 1876 Rosenblum² purposely infected psychotic and demented patients with relapsing fever; in the same year he published his observations that malaria frequently produces remissions in mental diseases. Zakon³ has furnished a translation of Rosenblum's original article, together with a photostatic copy of the Russian journal in which the paper appeared. The original is to be found in the Surgeon General's Library. A partial German translation of Rosenblum's article, by Oks,⁴ was published in 1879. The latter article attracted the attention of Dr. Peter Bassoe of Chicago, who in turn supplied the information to Dr. Neymann.

As chief of staff of the Odessa Psychopathic Hospital, Rosenblum had many opportunities to observe the effect of intercurrent febrile disease on various psychoses. In his review of such literature as was available to him, Rosenblum mentions among others Leidesdorf,⁵ who states "From personal observations I must conclude that febrile disease decreases the degree of psychic disturbance and that this action continues long after the cessation of the fever." This quotation assumes particular significance in view of the fact that Wagner-Jauregg,⁶ whose paper on "Prevention and Treatment of Progressive Paresis with Artificially Induced Malaria" in 1931 won him the Nobel Prize, worked as assistant in the psychiatric clinic of Leidesdorf during the years 1883 to 1889.

Rosenblum's report is based on observations on the effect of fever on psychoses in 32 cases; in 21 of these the psychosis was cured, in 3 the condition improved and in 8 it remained unchanged. Eight of the patients who were cured had far advanced melancholia; the others had various chronic forms of insanity. The author states that "the number of recoveries may seem too high, and I admit that some of the patients may relapse into their former state. It is possible too that some of the patients might have recovered without fever. However, although mindful of these possibilities, I still insist that febrile disease has a curative effect on the psychoses. This fact seems well proved."

In his original article Rosenblum reported that 12 cases in his series were observed during the epidemic of recurrent fever which took place in his city in 1874 and again in 1875. However, in a footnote on the

6. Wagner-Jauregg, J.: *Verhütung und Behandlung der progressiven Paralyse durch Impfmalaria*, Erg. Bd. d. Handb. d. experim. Therap., Munich, 1931.

fourth page of the German article the statement is made that "according to a personal communication of Rosenblum recurrent fever was produced in all these cases by inoculation of the patients with spirilla." Clinical experimentation of this sort was undoubtedly too advanced for the time; therefore he did not dare to describe the method but was forced to camouflage his experimentation under the guise of an "epidemic" of recurrent fever. It is apparent from reading the original article that he realized that it did not make much difference whether the fever was produced by an attack of typhoid, of malaria or of recurrent fever. His interest in the last named disease was probably due to the fact that it was easy to inoculate a patient with the spirilla of recurrent fever, because these organisms could be observed in a specimen of blood. Neymann believes that at least 10 of the cases represented an early stage of dementia paralytica and that possibly more were instances of syphilis of the central nervous system. It is impossible not to conclude with Neymann that Rosenblum was the first to appreciate the curative effect of fever itself on the psychoses and that he was the first to inoculate psychotic patients with the febrile disease. Possibly Wagner-Jauregg was not aware of the work of Dr. Rosenblum because of its publication in an obscure paper in a language little read outside the country of its origin.

THE INCIDENCE OF DIABETES IN SELECTEES

The analysis by Dr. Blotner and his associates¹ of the incidence of glycosuria among Massachusetts registrants for Selective Service is an extremely valuable study. While the figures in the article are impressive, they demand analysis and confirmation. The results of this study are puzzling, because the figures are much higher than those reported in the National Health Survey. Here is the incidence of diabetes in successive age groups in the Massachusetts material and in the age groups most closely corresponding in the National Health Survey of 1935-1936:²

Massachusetts Selectees		National Health Survey (Males)	
Age Group	Number of Diabetic per Thousand Registrants	Age Group	Number of Diabetic per Thousand
All ages.....	4.6	15-24	0.6
18-25.....	2.0	25-34.....	0.9
26-30.....	3.5	35-41.....	2.0
31-35.....	6.2		
36-40.....	6.1		
41-45.....	10.6		

If the Massachusetts data are at all representative, the incidence of diabetes among young adults is much greater than has hitherto been assumed on the basis

of earlier studies—at least three to four times as great as actually observed in the National Health Survey at ages under 25 and four to five times at ages 25 to 45. In part, the differences shown may be explained on the basis that known cases escape enumeration in population surveys as well as symptomless cases that have not come to diagnosis. In addition, a steady sizable increase in the incidence of diabetes at younger ages has occurred since the last survey was made as a result of the lessened mortality among young persons with diabetes, while the incidence of new cases may be presumed to be stable. There are, however, several reasons why one should hesitate to assume that the Massachusetts figures are representative. The chief general considerations from the statistical point of view are these: 1. The number of cases of diabetes in the sample is not large: 208 altogether. 2. The experience is largely urban. Previous studies³ have shown a significantly higher prevalence of diabetes in cities as compared with rural areas. Analysis of the Massachusetts data by density of population likewise indicates that the proportion with diabetes is appreciably lower in less thickly populated areas. 3. The ratios are particularly high also in men of racial stocks such as Jews and Irish, who form a much higher proportion of the Massachusetts population than that of the country as a whole. Among the men of native American stock there were about 3.5 with diabetes per thousand as compared with 4.6 in the experience as a whole. 4. It is significant that those known to be diabetic prior to examination numbered 42, or 1 per thousand. This ratio is practically identical with the figure for men between 20 and 45 in the National Health Survey. 5. The low proportion of overweights is surprising even though the weights are not previous maximum figures but as of the date of examination, and though obesity is less common among young diabetic patients than among those past 45.⁴ Moreover, follow-up study⁵ of a group of nondiabetic persons with glycosuria showed that even among the younger ones the proportion subsequently developing diabetes was much higher for overweight than for average weight or underweight patients. 6. The ratio of nondiabetic to diabetic persons with glycosuria is strikingly low—about 5 to 4. Unfortunately, no direct comparisons can be made with other material because the study under review excludes cases with a single positive specimen. 7. The Massachusetts figures for diabetes appear high in relation to the frequency of glycosuria among unselected men of the same age, as based on industrial, student, life insurance and periodic health examinations. It should be pointed out

4. Joslin, E. P.; Dublin, L. I., and Marks, H. H.: Studies in Diabetes Mellitus: IV. Etiology, *Am. J. M. Sc.* **191**: 759, **192**: 9, 1936.
5. Marble, A.; Joslin, E. P.; Dublin, L. I., and Marks, H. H.: Studies in Diabetes Mellitus: VII. Nondiabetic Glycosuria, *Am. J. M. Sc.* **197**: 533, 1939.

that only a fraction of the total among persons with glycosuria in these groups were diabetic. (a) Thus, among approximately 2,000 male employees of the Metropolitan Life Insurance Company under age 40 there were only 6 cases of glycosuria (0.2 per cent or over), or about 3 per thousand men. (b) A study of rejections for life insurance by the same company about ten years ago showed that 1.3 per thousand males at ages under 35 were refused Ordinary insurance because of glycosuria. (c) Dublin, Fisk and Kopf's⁶ analysis of results of periodic health examinations showed the following proportions of white males with "marked" glycosuria: at ages under 25 (mostly 18 to 25), 1 per thousand; ages 25 to 34, 3 per thousand; ages 35 to 44, 3 per thousand. (d) Sydenstricker's⁷ material of the same kind shows at ages 20 to 24, 1.1 per thousand; 25 to 29, 1.7 per thousand; 30 to 34, 2.2 per thousand; 35 to 39, 2.7 per thousand; 40 to 44, 5.2 per thousand. (e) Short and Ley's⁸ material of a similar nature but based on quantitative tests showed the following:

Glycosuria, 0.6 per cent or more:

Ages 20 to 29..... 1.9 per thousand

Ages 30 to 39..... 5.0 per thousand

Glycosuria, 1.1 per cent or more:

Ages 20 to 29..... 1.4 per thousand

Ages 30 to 39..... 3.6 per thousand

(f) The Cincinnati⁹ studies of white male office and industrial workers showed 9 per thousand with glycosuria (degree not specified). (g) Among 43,000 male college students there were only 33 with diabetes, or 0.7 per thousand.¹⁰

Apart from statistical considerations as to the general applicability of the Boston results, the incidence of diabetes in this study, largely based as it is on diagnoses from laboratory findings only, seems high on other grounds. The circumstances under which these men are examined are by no means ideal. The nervous tension attending the examinations undoubtedly gives rise to an increased number of transient glycosurias just as has been observed in college students during scholastic examinations¹¹ and in athletes immediately after a game.¹² Among the latter, hyperglycemia as

well as glycosuria has been noted.¹³ Again, many observers have called attention to the limitations of the dextrose tolerance test because it is an abnormal procedure and is influenced by a number of factors such as previous diet, infections and endocrine disorders.¹⁴ It is notable that most of the cases among Massachusetts registrants were symptomless and even by laboratory standards comparatively mild. The low incidence of obesity has also been mentioned.

Probably a significant proportion of the 166 cases among the registrants who were not previously known to be diabetic would be found on later examination not to have true diabetes. It is, no doubt, desirable that these men be disqualified or at least postponed for military service, but the final diagnosis in many instances might be deferred.

The study by Blotner and his associates, however, gives good evidence that our estimates of the incidence of diabetes may have to be revised upward by an appreciable amount. It would be a distinct service both for clinical and for statistical purposes if all these men, except those previously known to have diabetes, or at least the large number of borderline cases, were followed up and reexamined at suitable intervals to determine whether their metabolic abnormality persisted. Intensive study of these cases might prove valuable in other directions also.

FROZEN-DRIED NERVE GRAFTS

Supplementing his earlier experiments on rats, Paul Weiss¹ of the Department of Zoology, University of Chicago, has developed a successful technic for the transplantation of stored frozen-dried nerve grafts into cats, monkeys and other larger animals,² a technic presumably applicable to man. In order to avoid sacrificing a "minor" nerve for the repair of a "more vital" one, earlier experimenters tested the feasibility of transplanting stored, preserved or fixed nerve tissues. Most of these attempts were unsuccessful, presumably because of autolysis or other forms of denaturation of stored nerve segments. Weiss tried the method of immediately freezing and dehydrating the excised nerve segments, a method of preservation and storage used with success in other fields of biochemical research.³ Nerves dissected aseptically were dropped into isopentane immersed in liquid nitrogen ($-195^{\circ}\text{C}.$), where they were frozen instantaneously. The frozen nerve segments were then dehydrated for one week in high vacuum over phosphorus pentoxide at $-40^{\circ}\text{C}.$, after

which they were stored for several months in sealed sterile containers. Before use the stored dried grafts were rehydrated in Ringer's solution in vacuo. As a result of rehydration the stored grafts resumed their normal appearance and major histologic characteristics, including specific staining reactions.³

Rehydrated frozen-dried grafts from 1 to 3 cm. in length have thus far been transplanted into hindleg nerves of 21 rabbits, 20 cats and 81 monkeys. The most successful technic was without the use of sutures, the grafts being held in place by elastic sleeves cut from rehydrated, frozen-dried arteries of the same species. The elastic sleeves were fitted over the nerve ends by means of a special splicing instrument designed by the author. After this instrumental fitting the sleeves were held in place by clotted blood. Casts or other means of restraining active or passive movements were not usually found necessary.

Six grafts in cats and 21 grafts in monkeys have thus far been examined functionally from five and a half to ten months after the operation. Motor recovery was tested by observation of spontaneous and reflex movements and, by electrical stimulation of the exposed nerve. Among the 21 monkey grafts functional restoration was excellent in 8, good in 4, fair in 3 and poor in but 2 cases. Full recovery had occurred after the use of homoplastic grafts as well as macaque-to-spider grafts, in the latter case with perceptible delay. Cat-to-monkey grafts were unsuccessful. In a case in which full recovery occurred, tested 182 days after the operation, electric shock to the nerve trunk proximal to the graft gave strong contraction in intrinsic foot muscles at 320 mm. regeneration distance. Regeneration had thus proceeded at a minimum daily average of nearly 2 mm., including the graft and junction.

Microscopic studies of successful grafts have shown that the great mass of the regenerating fibers pass straight, unbranched, unobstructed across the gap into the distant stump and that there is neither fibrosis nor neuroma formation. The use of the arterial sleeve thus makes possible an orderly regeneration pattern, the majority of the fibers of a given fascicle remaining together and therefore reinnervating a relatively localized muscle group instead of being dispersed at random over the whole denervated periphery, as commonly happens after nerve suture.

Both nerve grafts and artery sleeves may be stored for at least four months in the frozen-dried condition without deterioration (longer storage has not yet been tested). Weiss therefore believes that banks of human nerves and artery sleeves of assorted sizes stored in the frozen-dried condition would be feasible in a modern hospital and valuable under present conditions caused by the war.

Current Comment

SIMILARITIES OF CERTAIN VIRUSES OF THE NERVOUS SYSTEM

The rickettsial, the smallpox, the influenzal and the poliomyelitic viruses represent different groups of closely related viruses to which can now be added the viruses of Russian spring-summer encephalitis and of louping ill. The encephalitis is a new clinical type observed by Russian investigators in thickly forested parts of Russia during May and June of recent years. The virus of this disease has been recovered from ticks (*Ixodes persulcatus*) and from wild rodents in certain regions. It has been passed experimentally by the tick from infected to healthy animals. It has been found¹ to be unrelated to other encephalitic viruses except that of the encephalomyelitis of sheep called louping ill. This virus can be transferred also from infected to healthy sheep by a tick (*Ixodes ricinus*). The comparative study of the viruses of the Russian encephalitis and of louping ill¹ show that they are closely related in complement fixation, neutralization and cross resistance tests as well as in the range and nature of their pathogenicity for animals. The Rockefeller Institute investigators regard the strains of the viruses they have studied as identical. The serum of a patient who became infected with either or both viruses while working with them responded in the same way to complement fixation and neutralization tests with the two. The serum of another patient who recovered from a laboratory infection with louping ill virus contracted in 1933 also gave similar positive results in tests with the two viruses. This establishment of definite groups or types of viruses will facilitate the study of the nature and scope of their pathogenic powers.

SEROLOGIC DIAGNOSIS OF RELAPSING FEVER

The diagnosis of relapsing fever may be difficult, since the symptoms resemble closely those of other diseases with intermittent fever. If pulmonary involvement is present the symptoms may be ascribed to other acute infectious diseases. From the blood of infected mice and rats Stein¹ has prepared a stable spirochetal antigen. Spirochete-containing blood was laked with saponin and the spirochetes were washed well with isotonic solution of sodium chloride. Suspensions of spirochetes obtained in this way were found to act as specific antigens in complement fixation and agglutination tests with serum from patients and animals infected with spirochetes of relapsing fever. Positive reactions were not obtained with serum of patients convalescent from other infections, e. g. typhus fever, malaria, Rocky Mountain spotted fever, Weil's disease, syphilis or typhoid. Stein's antigen merits further study, since it may prove to be useful in the diagnosis of relapsing fever.

MEDICINE AND THE WAR

In this section of The Journal each week will appear official notices by the Committee on War Participation of the American Medical Association, announcements by the Surgeons General of the Army, Navy and Public Health Service, and other governmental agencies dealing with medicine and the war, and such other information and announcements as will be useful to the medical profession.

ARMY

THE NEWTON D. BAKER GENERAL HOSPITAL

The new Newton D. Baker General Hospital, near Martinsburg, W. Va., covers 30 acres on a military reservation consisting of 186 acres. Construction was begun during 1943, and the first patients were admitted in January 1944. Over 700 patients are now receiving treatment at the hospital, and it will eventually accommodate 1,750 patients. The hospital is built on the standard plan of the Army's general hospitals, with certain variations. A two story administration building connects by corridors with the rest of the installation. Corridors connect all buildings, so that it is not necessary to expose the patient at any time to climatic changes. There are approximately eighty buildings, including those not corridor connected. The walls are of masonry, and construction is of a semipermanent type. An automatic fire control system has also been installed. The space between the buildings is laid out in avenues and streets. A chapel has been erected and a guest house, under the management of the Red Cross, where relatives of patients may secure lodging for a few days while visiting. Air conditioned wards are provided for postoperative cases. Water is secured from three wells, and that used for washing and cooking is softened. A gymnasium is now in the process of construction, as well as a theater building. Portable moving picture units are moved through the wards for bed patients. When fully completed, all wards containing patients unable to move will be wired for sound, so that entertainment broadcast from the patients' auditorium, or from outside, can be received by all.

Col. E. L. Cook is the commanding officer of the new hospital, and the permanent personnel will consist of several hundred officers, nurses and enlisted men.

BRIG. GEN. CONDON C. McCORNACK RECEIVES LEGION OF MERIT AWARD

Brig. Gen. Condon C. McCornack, formerly of Eugene, Ore., has been awarded the Legion of Merit for "exceptionally meritorious conduct in the performance of outstanding service. As surgeon of the Western Defense Command and Fourth Army from Nov. 12, 1940 to Jan. 26, 1943 his exceptional qualities of leadership, high professional knowledge, keen foresight and sound judgment enabled him successfully to effect the organization and administration of the medical service of the command, thus assuring the availability of necessary medical supplies and the finest medical care for the troops, most of which were located in isolated combat positions on the west coast of the United States, immediately after the declaration of war Dec. 8, 1941. As Deputy Chief of Staff, Western Defense Command and Fourth Army, from Jan. 27 to Sept. 14, 1943, and Deputy Chief of Staff, Western Defense Command, from Sept. 15 to Dec. 23, 1943, Colonel McCornack exhibited sound military judgment, tact and resourcefulness in the coordination of headquarters, staff functions, and in the planning and handling of many details incident to the preparation of two major task forces which subsequently engaged and routed the enemy with complete success from one of his strongholds in the Aleutian Islands and forced his evacuation from the other." Dr. McCornack graduated from Jefferson Medical College, Philadelphia, in 1904 and has been in the service since 1910.

CAPT. REUBEN E. ALMQUIST AWARDED LEGION OF MERIT

Capt. Reuben E. Almquist, formerly of Albert City, Iowa, has been awarded the Legion of Merit "for exceptionally meritorious conduct in the performance of outstanding services" in the Solomon Islands. His deeds were described in a communication from the United States Army headquarters in the South Pacific: "Frequently the only officer present to direct the care of casualties, Captain Almquist commanded a medical battalion's collecting company when the Japanese bombed Rendova Island on July 2. His collecting station was the only organized medical installation and he calmly and skilfully treated the wounded while bombers roared overhead. On Laiana beach and Munda sector, New Georgia, snipers frequently directed their fire at his station, but he refused to permit that to interfere with the care of the wounded. On Arundel Island Captain Almquist organized and efficiently operated a 50 bed hospital under difficult conditions." Dr. Almquist graduated from Rush Medical College, Chicago, in 1928 and entered the service Aug. 15, 1942.

LIEUT. STUART C. KNOX RECEIVES ARMY SILVER STAR

Lieut. Stuart C. Knox, formerly of Los Angeles, serving in the Medical Corps of the U. S. Naval Reserve, who has been in the South Pacific war theater during the last year, received from the War Department a citation "for unusual gallantry in action for administering first aid and evacuating more than 100 wounded men under fire in New Georgia" and was awarded the Silver Star Medal of the Army. Dr. Knox was with the Marines invading the New Georgia group July 1 to Aug. 26, 1943 and has seen action in several other battles in the South Pacific. He graduated from the College of Medical Evangelists, Loma Linda, Calif., in 1934.

THIRTEENTH CLASS OF AVIATION PHYSIOLOGISTS

Graduation exercises at the School of Aviation Medicine, Randolph Field, Texas, for the thirteenth class of Aviation Physiologists were held March 18. Brig. Gen. Eugen G. Reinartz, U. S. Army, commandant of the school, presented the certificates. The course in aviation physiology is of five weeks' duration. Among those graduating were the following officers of the medical corps:

1st Lieut. Hylan Arthur Bickerman, Forest Hills, N. Y.
1st Lieut. Ralph J. Greenberg, Chicago.
1st Lieut. Harvey A. Lewis, Long Beach, Calif.

PROMOTIONS IN THE ARMY MEDICAL DEPARTMENT

The War Department recently announced the promotion of Brig. Gen. Paul R. Hawley, College Corner, Ohio, and Brig. Gen. George C. Dunham, Portland, Ore., to the temporary rank of major general. Col. Stanhope Bayne-Jones, New Haven, Conn., and Col. Condon C. McCornack, Eugene, Ore., were promoted to the temporary rank of brigadier general.

NAVY

LIEUT. COMDR. ROBERT W. SKINNER III
AWARDED NAVY CROSS AND
PURPLE HEART MEDAL

Lieut. Comdr. Robert W. Skinner III, formerly of North Wales, Pa., was recently awarded two medals—the Navy Cross and the Purple Heart. The citation accompanying the Navy Cross award read "For extraordinary heroism while attached to the First Marine Raider Battalion during action against the Japanese forces in the Solomon Islands from Aug. 7 to Oct. 10, 1942. In the fierce battle for possession of Tulagi, Lieutenant Commander Skinner distinguished himself by his expert professional skill and dauntless courage, often in positions exposed to heavy enemy fire, in administering aid to the wounded and supervising the evacuation of casualties, with the result that there were no cases of infection and practically all of the wounded recovered. Later, when his battalion was fighting on Lunga Ridge, he voluntarily made at least three trips from the forward to the rear dressing station, traversing several hundred yards of exposed terrain frequently swept by hostile fire. He subsequently accompanied our forces in the second and third Matanikanu River battles, in the latter instance moving forward with the battalion, despite a badly injured knee. Lieutenant Commander Skinner's heroic conduct and valiant devotion to duty greatly contributed to the fighting efficiency of this battalion and were in keeping with the highest traditions of the United States Naval Service."

In the citation accompanying the Purple Heart award, it was related that Dr. Skinner was injured in the South Pacific area Sept. 27, 1942. He graduated from the University of Pennsylvania School of Medicine, Philadelphia, in 1938 and entered the service Dec. 16, 1940.

TWO OREGON NAVAL OFFICERS CITED

Lieut. (sg) William S. Gevurtz, formerly of The Dalles, Ore., has been cited by his commander for outstanding service while on the U. S. S. *Talbot*, when 178 survivors were rescued from another ship. The citation reads in part as follows:

... 38 were casualties requiring treatment. Many were of a serious nature, 19 having burns varying from less than 1 per cent to over 70 per cent of the body surface. Due to the professional skill, well planned preparations, essential organization and prior instruction of medical and first aid personnel, you were able to save all but 1 of the casualties received aboard. Further, the ship was under repeated air attack throughout the period of rescue, during which you and your medical detachment continued to function with no apparent concern for your own personal safety." Dr. Gevurtz graduated from the University of Oregon Medical School, Portland, in 1937 and entered the service in August 1941.

Lieut. Comdr. David E. Sullivan, formerly of Portland, Ore., was recently awarded the presidential unit citation for sinking more submarines than any other single unit in naval history. He has been flight surgeon on the U. S. S. *Card* for more than a year. Dr. Sullivan graduated from the University of Oregon Medical School, Portland, in 1940 and entered the service in September 1941.

NAVY'S NEWEST AND LARGEST HOSPITAL
SHIP INSPECTED

A delegation from the Navy Department, headed by Vice Admiral Ross T. McIntire, Surgeon General of the United States Navy, were received aboard the Navy's newest, largest and most modern hospital ship, the U. S. S. *Refuge*, on March 5 in a combined official inspection and "open house" to invited guests. The new hospital ship was converted from the troop transport U. S. S. *Kenmore* and was placed in commission on February 24. The complement includes twenty medical officers, three dental officers, five hospital corps officers, one volunteer specialist officer who will be in charge of the optical repair unit, the first of its kind on a hospital ship, twenty-nine navy nurses, an American Red Cross representative, which is another "first" as far as hospital ships are concerned, fourteen chief

pharmacist's mates and two hundred hospital corpsmen. The *Refuge* has fixed berths for 630 patients and carries aboard a mobile field hospital comprising 72 cots, a laboratory, x-ray equipment and necessary medical and surgical equipment and supplies. Each of the vessel's twelve wards has a surgical dressing room, diet pantry, utility room, linen locker, toilet and shower. The ship's main laboratory contains modern items of equipment such as a high speed centrifuge, a bacteriologic incubator, autoclaves, a refrigerator and other essentials. The library contains professional books and journals. The laundry is equipped with washing machines, spinners, tumblers, mangles and a steam press. Other features include a pharmacy, dental clinic, stationary and portable x-ray equipment, a complete physical therapy department and a clinic for eye, ear, nose and throat cases.

Comdr. M. A. Jurkops, New Brighton, N. Y., is commanding officer of the vessel and Capt. C. R. Wilcox is senior medical officer. Lieut. (jg) Mildred A. E. Marcan is chief nurse.

NEW DEPOT HOSPITAL OFFERS FACILITIES
IN EMERGENCY CASES TO
THE NAVY V-12 UNIT

Col. John Huling Jr., commanding officer of the Navajo Ordnance Depot, offered the use of the facilities of the new depot hospital in emergency cases of the Navy V-12 Unit. The depot's new 54 bed hospital is completely staffed and was dedicated at a ceremony February 15. A letter of appreciation to the depot commander from the commandant of the Eleventh Naval District at San Diego, Calif., read as follows: "The Medical Officer, Navy V-12 Unit, Arizona State Teachers College, Flagstaff, has informed this office that your hospital, through you, has offered to accept any emergency, surgical and orthopedic cases from the unit. Your willingness to assist and cooperate with the Navy in such a friendly way is sincerely appreciated."

LIEUT. ARTHUR T. WILLETTTS AWARDED
SILVER STAR MEDAL

Lieut. Arthur T. Willetts, a Navy doctor accompanying the Marine invaders of Bougainville and formerly of Verona, Pa., has been awarded the Silver Star Medal for gallantry in attending wounded under fire. The citation accompanying the award set forth that "Lieut. Willetts on last November 1, finding the beach strewn with injured men, established an aid station under cover of jungle growth and stuck to his station despite six enemy machine gun attacks." Dr. Willetts graduated from the University of Pittsburgh School of Medicine in 1937 and entered the service March 9, 1942.

MODIFICATION OF MAXIMUM AGE LIMIT
FOR APPOINTMENT AS ENSIGN

The Navy Department recently announced that the age limit contained in (a) Navy V-12 Bulletin No. 98 and NOPCL No. 11-43 and (b) Navy V-12 Bulletin No. 174 and NOPCL No. 12-43 has been modified in that qualified civilians who will have reached their 31st birthday by the time they may reasonably expect to graduate from medical or dental school are not eligible for appointment as Ensigns H-V(P) or induction and subsequent enlistment as Apprentice Seamen Class SV-12 or SV-12(S).

NAVY PERSONAL

Dr. Oswald S. Lowsley, New York City, recently returned from a tour of inspection of United States Naval Hospitals in his capacity as honorary consultant to the Medical Corps of the United States Navy. The tour included fourteen naval hospitals in the Middle West, on the Pacific Coast and on the Gulf of Mexico. In addition to making his inspection Dr. Lowsley addressed the medical officers of the various hospitals on "The Diagnosis and Treatment of Various Traumatic and War Injuries of the Organs of the Genital and Urinary Tracts."

MISCELLANEOUS

COMMITTEE ON THE MEDICAL RECORDS
OF THE FEDERAL GOVERNMENT
IN THE WAR

A study of the medical records created by agencies of the federal government during the last thirty years is being jointly conducted by the National Archives and the National Research Council with funds provided by the John and Mary R. Markle Foundation. This endeavor to determine the best method of dealing with the great mass of medical records, estimated at over 300,000 cubic feet in volume, that will have been accumulated before the end of the war was initiated by Dr. Solon J. Buck, archivist of the United States.

At present there are more than 900 hospitals and other units within the federal government that have records of the medical diagnosis, observation or treatment of individuals, digests and statistical summaries of such records, and records of medical research and experimentation. After a short time these records serve their initial purpose and are noncurrent so far as the unit that created them is concerned. There has, however, been no way of knowing how much of this material should be made available for research purposes through coordinated control and planning.

Under existing circumstances a physician doing research in a government hospital on one disease cannot possibly know what relevant material might be available at hundreds of other government hospitals. The Veterans Administration frequently must correspond with several hospitals to collect the medical records of one person. Scattered as they are, the records are simply inaccessible to any private investigator, no matter how zealous he may be.

On Dec. 6, 1943 the archivist called the attention of the Committee on Information, Division of Medical Sciences of the National Research Council, to the problems inherent in the government's accumulation of medical records. He declared that the general interest which the National Archives, the several federal agencies, the National Research Council and the medical profession have in the preservation and administration of the medical records of the federal government prompted him to lay before the committee a statement of the problem and to propose cooperative action by the Division of Medical Sciences and the National Archives with a view to its solution.

The archivist was of the opinion that the formulation of a comprehensive program for the medical records should be preceded by a thorough study of methods of creating and administering such records in the various agencies, the location, character, quantity and content of the various bodies of such records now in existence, and the nature and extent of the use that will or might be made of them. He proposed the designation of a committee within the Division of Medical Sciences of the National Research Council to supervise and conduct such a study and, on the basis of the facts collected, to make recommendations to him as to which of these medical records should be preserved and as to the best methods of administering the government's medical records so as to utilize their maximum scientific and administrative value.

The National Research Council authorized Dr. Lewis H. Weed, chairman of the Division of Medical Sciences, to appoint a committee. Those designated are Dr. George W. Corner, Baltimore, director of the Department of Embryology, Carnegie Institution of Washington, chairman; Dr. O. H. P. Pepper, University of Pennsylvania; Dr. Samuel C. Harvey, Yale University, and Dr. Harry Solomon, Harvard University. The following have been assigned by the various government services: Army, Surgeon General's Office, Col. A. G. Love; Adjutant General's Office, Col. R. M. Levy; Navy, Bureau of Medicine and Surgery, Capt. H. H. Montgomery; U. S. Public Health Service, Dr. S. D. Collins; Veterans Administration, Dr. Martin Cooley; Bureau of the Budget, Mr. Elbridge Sibley, and Mr. Dan Lacy, National Archives. Dr. R. K. Burns Jr., Department of Embryology, Carnegie Insti-

tution of Washington, is secretary. At its first meeting the committee restricted the study to include only medical records created in the last thirty years.

It was also decided to visit and survey a selected group of representative hospitals and other agencies of the government among the several departments and bureaus creating medical records. This will make it possible to study records of hospitals of all types and to collect information concerning the creation and flow of records from field units to the departmental level.

It is hoped that the information collected during the survey will enable the committee to determine the potential value of these medical records for research. Which of the records should be preserved to meet the research needs of the government and of private medical scholars? Will the interests of citizens and government be best served by leaving the records at scattered points or would it be more economical and increase the usefulness of the records to centralize them at some one place? Would centralization reveal latent values for technical medical research that have never been exploited? These and a host of other questions concerning the records are of vital interest to the medical profession in general.

If the committee's recommendations contain answers to the majority of these questions, it will contribute materially to the solution of the relatively new but already perennial question of what should be done about medical records; it will also help the archivist of the United States to round out post-war plans for an orderly retirement of the mass of records that may be left without an owner or sponsor when the war is over and the emergency agencies as well as the armed services are demobilized. It will have demonstrated a means whereby the archivist can avail himself of professional knowledge and experience not available to him on his own staff. But most important of all, the committee has the opportunity on behalf of the medical profession to guard against the dispersal of records which should be preserved in the interest of medical science.

EXHIBITION OF "OCCUPATIONAL THERAPY
IN WAR AND PEACE"

The Philadelphia Art Alliance, with headquarters at 251 South 18th Street, will present from April 17 to May 30 the country's most representative exhibition of "Occupational Therapy in War and Peace." Every gallery and showcase in the Art Alliance will be taken over for the six weeks by this exhibit, which is under the direction of Miss Kathryn Wellman and a large committee. Regular demonstrations by actual occupational therapy patients will be given for the benefit of the public in the various rooms of the Art Alliance. One gallery will house a model occupational therapy shop as might be found in a civilian hospital, with finished and unfinished handicraft on view. Incapacitated patients will demonstrate in this shop every Saturday afternoon, and at that time Miss Wellman will be on hand to answer questions.

In another gallery of the Art Alliance, which will be set up as a functional shop, service patients from the Valley Forge General and the U. S. Naval Hospital will demonstrate the crafts which introduce exercise. These demonstrations will be held on Tuesday afternoons. The Art Alliance's regular Decorator's Gallery will be converted into a modern living room with furniture and furnishings constructed by occupational therapy patients in Army, Navy and civilian institutions. Other exhibitions will feature occupational therapy working materials, finished products, large photographs of patients at work and of their progress, and civilian made articles for sale. During the six weeks, all of the Art Alliance events will center about occupational therapy. These will take in Army and Navy technical discussions, talks on "Design in Salvage," "Muscle Therapy," "Creative Stitchery," "Group Occupational Therapy in Group Psychotherapy," "Occupational Therapy in the Pacific Area," "Rhythmic Exercises for Amputees" and three films from the British Information Service.

OFFICE OF CIVILIAN DEFENSE MEDICAL EQUIPMENT AND SUPPLIES

The Office of Civilian Defense recently issued a release dated February 15, supplementing notice dated July 1, 1943, on the Care and Maintenance of Mobile Medical Team and Casualty Station Equipment, in which it is stated that bonded state and local property officers are both accountable and responsible for federally owned medical supplies and equipment, and when a state or local chief of Emergency Medical Service accepts delivery of supplies and equipment from a property officer he becomes responsible therefor. Responsibility for the distributed supplies is transferred to the persons and institutions receiving them, provided the property officer is notified. A person having custody of federal property will not be held financially liable for its loss or damage unless such loss or damage occurs as a result of his negligence or abuse. Periodic inspections of all medical supplies and equipment should be made by mutual agreement.

The regional medical officer is held responsible for the supervision of U. S. P. H. S. plasma reserves, and property officers have no responsibilities in connection with plasma.

The U. S. Bureau of Narcotics is responsible for inspection of morphine reserves. Chiefs of Emergency Medical Service and property officers will recognize that agency's over-all responsibility for the control of narcotics.

RESPONSIBILITY OF REGIONAL MEDICAL OFFICERS

The regional medical officer will inquire concerning and, when possible, will inspect lent medical equipment, and he will advise the regional property officer concerning the technical care and maintenance of medical equipment. The regional medical officer will advise state chiefs of Emergency Medical Service and through them local chiefs concerning their duties with OCD medical property. The regional medical officer will report to the regional property officer any apparent neglect of federal equipment of which he may have knowledge. The regional medical officer will call to the attention of the state chief of Emergency Medical Service any evidence of ineffective local distribution. During emergency periods the regional medical officer with the approval of the regional director will direct interstate transfer of OCD medical equipment and supplies.

RESPONSIBILITIES OF STATE CHIEFS OF EMERGENCY MEDICAL SERVICE

The state chief of Emergency Medical Service is responsible to the State Defense Council and citizens of the state for taking appropriate steps to see that medical equipment is available and ready for use.

ARMY-NAVY E AWARDED TO ANSCO

AnSCO, Binghamton, N. Y., America's oldest manufacturer of photographic materials, was recently awarded the Army-Navy E for "great accomplishments in the production of war equipment." Since Pearl Harbor approximately 75 per cent of AnSCO's production has been for the government and essential war industries. Its camera plant is now exclusively engaged in the manufacture of precision instruments for the Army Air Forces and the Navy. Included in its wartime production are sextants which permit fliers to determine their position anywhere over the earth's surface under all weather conditions.

AMERICAN RED CROSS SHIPS GAUZE FOR 164 MILLION DRESSINGS

Surgical gauze for 104 million dressings has been requisitioned by the American Red Cross from U. S. Army medical supply depots and will be shipped to approximately two hundred larger Red Cross chapters throughout the country for processing. In addition, gauze for 60 million more surgical dressings has been ordered direct from manufacturers to be shipped to more than one thousand smaller chapters. Volunteers now are producing more than three million dressings daily to provide stocks wherever United States troops are in action. One billion dressings have been produced by the American Red Cross in the past two years.

HOSPITALS NEEDING INTERNS AND RESIDENTS

The following hospitals have indicated to the Council on Medical Education and Hospitals that they have not completed their house staff quota allotted by the Procurement and Assignment Service:

(Continuation of list in THE JOURNAL, April 1, p. 993)

CALIFORNIA

St. Joseph's Hospital, San Francisco. Capacity, 289; admissions, 7,218. Sister M. Raymond, Superior (assistant residents—April 1, July 1).
St. Luke's Hospital, San Francisco. Capacity, 225; admissions, 6,678. Dr. Howard H. Johnson, Director (assistant residents—October 1).

ILLINOIS

St. Francis Hospital, Peoria. Capacity, 593; admissions, 14,093. Sister M. Ancilla, R.N., Superintendent (interns—October 1).

MISSOURI

Alexian Brothers Hospital, St. Louis. Capacity, 176; admissions, 1,976. Brother Athanasius, R.N., Superintendent (resident—April, October 1).

NEW YORK

Cumberland Hospital, Brooklyn. Capacity, 400; admissions, 6,205. Dr. Max Seide, Superintendent (3 interns—October 1).

OHIO

Aultman Hospital, Canton. Capacity, 180; admissions, 6,332. Mr. James W. Stephan, Director (interns, residents).

WASHINGTON

Eastern State Hospital, Medical Lake. Capacity, 2,200; admissions, 614. Dr. M. W. Conway, Superintendent (resident—psychiatry—October 1).

COMMUNITIES IN NEED OF PHYSICIANS

The United States Public Health Service has recently announced that the following four communities have applied for federal assistance in obtaining the services of physicians under the recently enacted law authorizing an appropriation of \$200,000 for the relocation of physicians:

Hamilton (Harris County), Georgia.
Neosho (Newton County), Missouri.
Pineville (Mecklenburg County), North Carolina.
Star (Montgomery County), North Carolina.

Physicians interested in locating in these communities should communicate with the Surgeon General, United States Public Health Service, Washington (Bethesda Station), D. C.

WARTIME GRADUATE MEDICAL MEETINGS

Additional subjects and speakers for Wartime Graduate Medical Meetings have just been announced:

At Indiana University School of Medicine, Indianapolis: Management and Prognosis in Head Injuries, Dr. R. L. Glass, April 10; Investigation of Sterility, Dr. C. P. Huber, April 10.

Dr. Barnard Horton, Rochester, Minn., will speak on his recent studies on multiple sclerosis April 17 in Columbus, Ohio, for the combined medical personnel at Fort Hayes and the Lockbourne Air Base. On April 18 he will present the same subject before the medical personnel at Patterson Field and at Wright Field and the Dayton Academy of Medicine.

INCREASING PENICILLIN PRODUCTION

The War Production Board recently announced that representatives of twenty-one producers have authorized a committee from their industry to explore, with the War Production Board, various forms of agreement for the exchange of technical information and patents in endeavoring to increase penicillin production. The committee is to study possible contract forms and recommend an agreement between producers and WPB, which, it is hoped, may be concluded soon. In granting authority for the explorations of the committee, producers' representatives expressed themselves as desirous of doing everything possible to increase the production of penicillin within the shortest period of time. The committee members are A. H. Friske, Eli Lilly and Company, Indianapolis; H. C. Fritsch, Parke, Davis and Company, Detroit; Carleton H. Palmer, E. R. Squibb & Sons, New York; Dr. John Reichel, Reichel Laboratories, Inc., Kimberton, Pa., and Kenneth H. Hoover, Commercial Solvents Corporation, Terre Haute, Ind.

ORGANIZATION SECTION

OFFICIAL NOTES

COUNCIL ON MEDICAL SERVICE AND PUBLIC RELATIONS

Washington Information Office Established

The resolution of the Council relative to the opening of an Office of Information in Washington, passed at the February meeting and submitted to the Board of Trustees for approval, has received the unanimous sanction of that body.

The office will be under the direction of the Council and Secretary and in direct charge, for the time being, of Dr. Joseph S. Lawrence of Albany, N. Y., who has represented the New York State Medical Society in Albany for over twenty years. A large number of booklets, pamphlets and other published material are being sent to Washington, where they will be readily available to those desiring information concerning the various fields of medicine and the activities of the American Medical Association. The Council will continue its Chicago office as usual, and its semimonthly bulletin will be prepared in that office.

The location of the office in Washington is in suite 900 of the Columbia Medical Building, 1835 I Street Northwest. The date of opening was April 3.

DOCTORS AT WAR

Radio broadcasts of Doctors at War by the American Medical Association in cooperation with the National Broadcasting Company and the Medical Department of the United States Army and the United States Navy are on the air each Saturday at 4:30 p. m. Eastern war time (3:30 Central war time, 2:30 Mountain war time and 1:30 Pacific war time).

The titles and guest speakers for the next three programs are as follows:

April 8. "Men with New Faces."

Speaker, Major General D. N. W. Grant, M. C., A. U. S., Air Surgeon A. A. F., Washington, D. C.

April 15. "Decks Aflame."

Speaker, Capt. French Moore (MC), U. S. N., Washington, D. C.

April 22. "Cadet Nurse Recruiting."

From Washington, D. C.

WOMAN'S AUXILIARY

Arkansas

The Allen County auxiliary honored Mrs. L. J. Kominsky, state president, at a luncheon. Mrs. Kominsky discussed the two new national committees, the Doctors' Aid Corps and the War Work Committee. Mrs. William Hibbitts, member of the national board, discussed the Wagner bill.

Colorado

The board of management of the Woman's Auxiliary to the Colorado State Medical Society held its midyear business meeting at the home of the president, Mrs. Lawrence T. Brown, Denver.

The Denver County auxiliary met in January at the Nurses' Home of the Denver General Hospital. Books were contributed to the Nurses' Library.

The Medical Auxiliary of Northeastern Colorado met on January 13. After a business session a review of Josephine Lawrence's book "There is Always Today" was presented.

Florida

At a recent meeting of the Polk County auxiliary the wives of doctors at the Bartow Air Base and Drane Field, and the auxiliary members whose husbands are in service, were honored at a social in Lakeland.

Indiana

The annual guest dinner of the Vigo County auxiliary was held recently. A play was read by Mrs. Grace Moorehead.

Kansas

The Saline County auxiliary recently gave a luncheon in honor of the state president, Mrs. E. E. Tippin of Wichita. Mrs. Oliver Ebel spoke on "Medical Headlines and Oddities."

Rice County auxiliary entertained the Medical Society with a buffet supper recently in Sterling.

Shawnee County auxiliary entertained in January with a dessert luncheon in Topeka. Dr. H. L. Herbert of the Kansas Board of Health discussed "Modern Attacks of Tuberculosis."

The Wyandotte County auxiliary met in January. Dr. W. H. Pickett of the department of health spoke on "Medicine Up to Date." In February the Wyandotte Auxiliary held its annual

Public Relations Test at Bethany Hospital Nurses' Home in Kansas City. Mr. Oliver Ebel, executive secretary of the Sedgwick County Medical Society, was the guest speaker.

The Marshall County auxiliary had election of officers at the February meeting.

Minnesota

The midyear board meeting of the Minnesota auxiliary was held in February. Mrs. F. S. McKinney, state president, organized a new auxiliary, that to the Waseca Medical Society. Mrs. S. C. Oeljen was elected president and Mrs. B. J. Gallegar secretary-treasurer.

Mississippi

Mrs. Temple Ainsworth was made general chairman of arrangements for the state convention of the Central Auxiliary of Mississippi, which will meet in Jackson. Mrs. A. L. Gray is president of the auxiliary. Mrs. R. L. Simmons was elected president of the East Mississippi auxiliary, and Mrs. J. Rice Williams of Huston was elected president of the Northeast Mississippi auxiliary.

South Carolina

The Woman's Auxiliary to Oconee County Medical Society and the Pickens County auxiliary held meetings recently. At both meetings Mrs. D. L. Halford, tuberculosis worker for Oconee and Pickens counties, spoke on tuberculosis work in South Carolina.

MEDICAL LEGISLATION

STATE MEDICAL LEGISLATION

New Jersey

Bill Introduced.—S. 199 proposes to authorize the state department of health, and the local boards of health within their respective jurisdictions, to require any person suspected of being infected with a communicable disease to submit to a medical or roentgenologic or laboratory examination and to permit such specimens of blood and bodily discharges, secretions or excretions to be taken as may be necessary to establish the presence or absence of the disease.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Dr. Roy Kracke Named Dean at Alabama.—Dr. Roy R. Kracke, professor of pathology and bacteriology and chairman of the department at Emory University School of Medicine, Atlanta, Ga., has been named dean of the new Medical College of Alabama to be organized in Birmingham (THE JOURNAL, March 4, p. 658). Dr. Stuart Graves, who has been dean of the two year school at the University of Alabama School of Medicine, University, during the transition period of the development of the two year school into a four year college, will remain as dean of the school of basic medical sciences. He will also continue as an adviser on student health, acceptance of medical students and development of the new medical college. Dr. Kracke was born in Hartselle, Dec. 5, 1897. He attended Alabama Polytechnic Institute, Auburn, and in 1924 received his bachelor's degree from the University of Alabama. He received his degree in medicine at the Rush Medical College in 1928. He spent a year in 1925 at the University of Alabama, University, as instructor in pathology. He later was appointed to Emory University as instructor in pathology, subsequently serving as assistant professor, associate professor and professor of pathology, bacteriology and laboratory medicine. In 1934 he was awarded the certificate of merit by the American Medical Association for his exhibit showing original investigation for his work illustrating the knowledge of etiology of granulocytopenia and in 1935 the gold medal of the American Society of Clinical Pathologists for his work on agranulocytic angina. He has written extensively and is author of "Diseases of the Blood and Atlas of Hematology" (with Hortense Garver). Dr. Graves, who graduated at Syracuse University College of Medicine, New York, in 1911, has been serving as dean and professor of pathology at Alabama since 1928. He was also acting state health officer for Alabama from 1929 to 1930. Prior to joining the faculty of Alabama he had been professor of pathology and bacteriology at the University of Louisville School of Medicine from 1914 to 1928, serving as dean of the medical school from 1922 to 1928. As the plans progressed for the development of the new four year school, Dr. Graves urged the university administration to secure a younger man for the project because of the fact that he was approaching the retirement age.

ARIZONA

State Medical Meeting.—The Arizona State Medical Association will hold its annual meeting at the Hotel Westward Ho in Phoenix, April 14-15, under the presidency of Dr. Otto E. Utsinger, Ray. Members of the faculty of the University of Southern California School of Medicine, Los Angeles, will present the program. On Friday evening a session will be devoted to a discussion of Coccidioides by Drs. Edward M. Butt and Arthur M. Hoffman. Saturday the program will be conducted by Drs. Frederick J. Moore, Philip I. Cummane and Gurth Carpenter.

CALIFORNIA

Joint Session on Tuberculosis.—The California Tuberculosis Association and the California Trudeau Society met at the Biltmore Hotel, Los Angeles, March 28-30. Among the guest speakers were Drs. John Alexander, professor of surgery, University of Michigan Medical School, Ann Arbor, and Henry S. Willis, pathologist and superintendent of William H. Maybury Sanatorium, Northville, Mich. Among the topics to be discussed by the guests were "Practical Considerations Regarding Thoracoplasty" and "Perspective and Trends in Tuberculosis."

Court Issues Writ Restraining State Board in Abortion Case.—The San Francisco Superior Court has ruled that the state board of medical examiners acted illegally when it moved to revoke the license of Dr. Chester D. Sewall, Redding, on a charge of performing two illegal operations, newspapers reported recently. Judge Theresa Meikel issued the ruling on a mandamus action filed on behalf of Dr. Sewall shortly after the medical board on July 1, 1942 declared him guilty on two

counts. Judge Meikel held that a permanent writ would be issued restraining the medical board from proceeding further with the case. A preliminary writ was issued in November 1942.

DELAWARE

Society News.—A symposium on peptic ulcer was presented before the New Castle County Medical Society, Wilmington, March 21 by Drs. Lawrence J. Rigney and John C. Pierson, Wilmington. Major Maurice A. Schnitker, M. C., A. U. S., also addressed the society on "Significance of Ulcer in Armed Forces."

FLORIDA

State Medical Meeting in St. Petersburg.—The seventy-first annual meeting of the Florida Medical Association will be held at St. Petersburg, April 13-14, with headquarters at the Princess Martha Hotel and under the presidency of Dr. Eugene G. Peek, Ocala. Dr. Edgar G. Ballenger, president-elect of the Southern Medical Association, Atlanta, Ga., will address the first general session, Thursday, on "The Relationship of Obstructive Lesions to Urologic Affections." Included among the other speakers will be:

- Capt. Theodore L. L. Soniat, M. C., A. U. S., Psychiatric Experiences in an Army Air Base Hospital.
- Capt. Millard B. White, M. C., A. U. S., Penicillin.
- Capt. Morris B. Guthrie, M. C., A. U. S., Primary Atypical Pneumonia: Analysis of 150 Cases.
- Dr. Duncan T. McEwan, Orlando, Refrigeration Anesthesia of the Extremities: Its Application, Use and Case Reports.
- Lieut. Comdr. Carroll J. Fair (MC), U. S. Naval Reserve, Gynecologic Problems Beginning at Forty.
- Dr. Henry C. Sweany, Chicago, The Challenge of Tuberculosis to the Physician.
- Dr. Walter I. Lillie, Philadelphia, Fundus Changes in Arterial Hypertension.

Specialty groups meeting during the session will include the Florida section of the American College of Physicians, the Florida Society of Ophthalmology and Otolaryngology, the Florida Association of Industrial Surgeons, the Florida Society of Dermatology and Syphilology, the Florida Radiological Society and the Florida Pathological Society. The eighteenth annual meeting of the woman's auxiliary to the state medical society will be held at the Army and Navy Club, April 14.

ILLINOIS

Citizens' Public Health Committee.—A citizens' public health committee was organized in St. Clair County February 22. The new group is educational in nature and will attempt to familiarize citizens with the legislation affecting health units.

Chicago

The Lewis Linn McArthur Lecture.—Dr. Thomas Grier Miller, professor of clinical medicine, University of Pennsylvania School of Medicine, Philadelphia, will present the twentieth Lewis Linn McArthur Lecture of the Frank Billings Foundation, Institute of Medicine of Chicago, at the Palmer House, May 26. His paper will be entitled "Observations on the Human Digestive Tract by Intubation."

Survey Nearing Completion for Medical Center.—The medical center commission named by the state legislature in 1941 to develop a medical center in the area bounded by Congress Street, Roosevelt Road, Ashland and Oakley avenues, is completing a survey of more than 2,200 parcels of privately owned property. A meeting was held March 16 by the commission to discuss plans for expanding the medical center near the Cook County Hospital.

Maternity Center Has New Library.—The Chicago Maternity Center recently dedicated its library, made available by the financial gift of the family of Mrs. Lena K. Witkowsky, for whom the library has been named. The library will be for use of the staff, medical students and nurses. This is the first time in the years since the center was established in 1897 that it has had its own library; the only collection heretofore available was one given by the late Dr. Joseph B. De Lee.

The Capps Prize.—On recommendation of the committee on the Joseph A. Capps Prize, the board of governors of the Institute of Medicine of Chicago announces that no award was made for 1943. Manuscripts for the current competition must be submitted to the secretary of the institute, 86 East Randolph Street, not later than December 31. Competition is open to graduates of Chicago medical schools who completed their internship or one year of laboratory work in 1942 or thereafter. The prize consists of \$400 for the most meritorious investigation in the specialties of medicine. The investigation may be also in the fundamental sciences, provided the work has a definite bearing on some medical problem.

Lectures on Popular Science.—A series of lectures on popular science and technology is being given at the Museum of Science and Industry, Jackson Park, April 7-May 26. Dr. Milan V. Novak, professor and acting head of the department of bacteriology and public health, University of Illinois College of Medicine, gave the first lecture, on penicillin. Others in the series will include one April 28 by Dr. Ralph W. Gerard, professor of physiology, University of Chicago School of Medicine, on "Biological Aspects of War and Peace" and one May 5 by Dr. Andrew C. Ivy, Nathan Smith Davis professor of physiology and head of the department, Northwestern University Medical School, on "Aviation Calls the Doctor."

Arquin Fund for Clinical Research.—The board of governors of the Institute of Medicine of Chicago has accepted the custody of a memorial fund collected by friends and associates of Dr. Sergius F. Arquin, who died Dec. 8, 1928 as a result of epidemic cerebrospinal meningitis while an intern at Cook County Hospital. The income from the fund is to be used as a prize for investigative work or as a contribution toward the cost of publication or illustration of such work, or for related assistance in clinical research carried on by an intern or resident in Cook County Hospital or other local hospitals. Applications should be addressed to the secretary of the Institute of Medicine of Chicago, 86 East Randolph Street, Chicago 1.

INDIANA

Personal.—Col. Frederick C. Potter, head of the pathology department at Billings General Hospital and for many years associate professor of nervous and mental diseases, Indiana University School of Medicine, Indianapolis, has been granted honorary membership in the Indianapolis Medical Society.—Dr. Robert E. Lyons Jr., formerly a major in the army, who recently received a medical discharge, has reopened his office in Bloomington, where he will resume his private practice.

Physician Honored.—Dr. Bonnelle W. Rhamy, Fort Wayne, was guest of honor at a dinner at the Fort Wayne Country Club, February 10, celebrating his seventieth birthday, February 11. Dr. Rhamy in 1905 opened the Fort Wayne Medical Laboratory, which he has conducted ever since. A congratulatory scroll was presented to the physician, whose work has included the invention of a method of preservation of complement by the addition of sodium acetate, a triple stain for use in staining frozen sections and a method for the cultivation of *Pasteurella tularensis*.

KENTUCKY

Library Named for Physician.—The library in the new \$80,000 Campbell County Health Center, Covington, has been named in honor of Dr. Claude Youtsey, Newport, who died March 5, 1943. At the dedication exercises a life size picture of Dr. Youtsey and a memorial plaque were presented to the center. Dr. Youtsey, as chairman of the county health board for many years, was instrumental in obtaining federal and state aid which made the building of the health center possible, the Covington Post reported March 6.

MAINE

Campaign Against Tuberculosis and Cancer.—The Maine Public Health Association this month is carrying on its annual early diagnosis campaign for the prevention of tuberculosis, and the Maine Division of the Women's Field Army is directing its annual drive for funds for cancer control. The theme for the tuberculosis program for this year, sponsored by the National Tuberculosis Association, is the promotion of chest x-ray examinations for war essential workers.

MICHIGAN

Protein Research.—A new series of studies on protein metabolism will be inaugurated soon at the Wayne University College of Medicine, Detroit, to be carried on under the supervision of Dr. John W. Hirshfeld, assistant professor of surgery, and Arthur H. Smith, Ph.D., professor of physiologic chemistry. The project will be financed by the United States government through the Office of Scientific Research and Development.

Laboratory Services Extended to Include Identification of Paratyphoid.—The laboratories of the state health department in Lansing are now aiding physicians in the state in identifying some of the rarer types of paratyphoid fever. The laboratories are the sixth in the United States to give this service, according to *Michigan Public Health*. Heretofore cultures have been sent by the department to laboratories of the University of Kentucky, Lexington, first in the United States to undertake these studies, it is stated.

Personal.—Dr. Samuel G. Albert, who recently received an honorable discharge from the U. S. Army, has begun the practice of medicine in Ironwood.—Dr. Charles L. Hess, Bay City, has been appointed to succeed Dr. Roy C. Perkins, Bay City, on the state advisory council of health.—Dr. and Mrs. Sherman L. Loupee, Dowagiac, observed their fiftieth wedding anniversary March 5.—Dr. Emily L. Ripka-Hautau, Roscommon, has been chosen health officer of Midland County to succeed Dr. Ralph R. Sachs, who has moved to Richmond, Wash.

Graduate Courses.—On March 9 the annual postgraduate program for graduates in medicine opened under the auspices of the Michigan State Medical Society in cooperation with the University of Michigan Medical School, Ann Arbor, Wayne University College of Medicine, Detroit, the state department of health and the Wayne County Medical Society, Detroit. The various courses will be conducted intermittently until May 26, covering a wide range of subjects. Additional information may be obtained from the committee on postgraduate education, Michigan State Medical Society, Room 2040, University Hospital, Ann Arbor.

MISSISSIPPI

Personal.—Dr. Joseph Howard Beard Jr., Urbana, Ill., has been lent by the U. S. Public Health Service to become health officer of Wilkinson County to succeed Dr. Robert M. Wingard. The latter has been assigned to Mobile, Ala., on a public housing project.—Dr. Samuel E. Eason, New Albany, was recently elected president of the Mississippi State Board of Health, succeeding Dr. James W. Lipscomb, Columbus.

Southwest Allergy Forum.—An informal round table conference will be conducted by the Southwest Allergy Forum in Jackson, April 15-16. Among the leaders in the conference will be:

- Dr. Edley H. Jones, Vicksburg, Vasomotor Rhinitis.
- Dr. Joseph S. Shavin, Shreveport, La., Angioneurotic Edema and Urticaria.
- Dr. Bernard G. Efron, New Orleans, Evaluation of Systemic Reaction.
- William T. Penfound, Ph.D., New Orleans, Pollination of Anemophilous Trees in New Orleans.
- Dr. Ralph Bowen, Houston, Texas, Seasonal Hay Fever Due to Tree Pollens.
- Dr. Homer E. Prince, Houston, Differential Diagnosis of Bronchial Asthma in Infants and Young Children.
- Dr. Herbert J. Rinkel, Kansas City, Mo., Diagnostic Regimen in Food Allergy.
- Dr. Fannie L. B. Leney, Oklahoma City, Practical Consideration of Contact Dermatitis as Seen by the Allergist.
- Dr. Orval R. Withers, Kansas City, Headache as an Allergic Problem.
- Major Lawrence J. Halpin, M. R. C., Treatment of Poison Ivy Dermatitis.

NEW YORK

Fund for Research in Clinical and Preventive Medicine.—An anonymous contribution has been given to Cornell University to endow a scholarship to be known as the Veranus A. Moore Research Fund in honor of the former dean of the state veterinary college in Ithaca. The income from the fund will be used for research in clinical and preventive medicine. Dr. Moore died in 1931.

Graduate Lectures.—The Cortland County Medical Society will be addressed April 21 by Dr. Harold J. Stewart, New York, on "Use of the Electrocardiogram in Heart Disease" and May 19 by Dr. Stearns S. Bullen, Rochester, on "Asthma." Dr. Stockton Kimball, Buffalo, will discuss "Malaria and the Dysenteries" before the Steuben County Medical Society, Corning, April 13. The lectures are part of a cooperative program of the state medical society and the state department of health.

New York City

The Harvey Lecture.—Earl A. Evans Jr., Ph.D., professor of biochemistry, University of Chicago, will deliver the seventh Harvey Society Lecture of the current series at the New York Academy of Medicine, April 20. He will discuss "Carbon Dioxide Fixation in Animal Tissues."

William Henry Welch Lectures.—Dr. Frank C. Mann, Rochester, Minn., delivered the William Henry Welch lectures at Mount Sinai Hospital, April 3-4. His subjects were "Studies on the Dehepatized Animal: A Review" and "Restoration and Pathologic Reactions of the Liver."

Birthday Celebration in Honor of Dr. Castiglioni.—The seventieth birthday of Dr. Arturo Castiglioni, professor of the history of medicine, Yale University School of Medicine, New Haven, and president of the New York Society for Medical History, will be observed at a dinner in the Starlight Roof, Waldorf-Astoria Hotel, April 12. An anniversary

volume will be presented to Dr. Castiglioni as a memento of the occasion. Dr. Castiglioni was born in Trieste, Italy, April 10, 1874. He received his medical degree at the University of Vienna in 1896.

Conference on Convalescence and Rehabilitation.—The second national conference on convalescence and rehabilitation will be held at the New York Academy of Medicine, April 25-26, under the auspices of the committee on public health relations of the academy and the support of the Josiah Macy Jr. Foundation. Representatives of all military services will be included in the program, which will deal with such topics as motivation, retraining, research and the role of home, hospital and industry. Admission will be by invitation. Edward H. L. Corwin, Ph.D., is executive secretary of the academy.

City Hospital and New York Medical College Establish Teaching Affiliation.—A teaching affiliation has been established between the City Hospital of the department of hospitals and the New York Medical College. According to an announcement by Dr. Edward M. Bernecker, city commissioner of hospitals, and Dr. J. A. Werner Hetrick, dean of the New York Medical College, extensive clinical facilities in medicine, surgery, obstetrics, gynecology, neurology and pathology will now be available to students of the medical college. The hospital is located on Welfare Island adjacent to the Metropolitan Hospital, which is also used for teaching purposes by the college. The city hospital was founded in 1832. It now has accommodations for 880 beds, averaging 10,000 admissions a year with an average stay of twenty-three days. About 30 per cent of the patients have chronic diseases. The hospital maintains jointly with the Metropolitan Hospital an outpatient department at 80th Street and East End Avenue. Coincident with the start of the new arrangement is the appointment of a number of physicians to the clinical faculty of the medical college.

Program to Develop Postwar Services at Mount Sinai Hospital.—With the appointment of Dr. George Baehr as director of clinical research and of Dr. Isidore Snapper as director of graduate medical education, a far-reaching program of expansion and reorganization has been launched at Mount Sinai Hospital to prepare for postwar responsibilities. The two positions are newly created ones. While the new appointments are the first steps in the program of expansion, later developments will include enlargement of the hospital's clinical and laboratory facilities and the creation of a number of full time paid fellowships for promising young physicians and research workers. Mount Sinai began its work as a teaching institution in 1872, when the first interns were appointed to its house staff. In 1910 the hospital began undergraduate medical instruction, opening its facilities to students of the Columbia University College of Physicians and Surgeons. In 1923 this affiliation was expanded to postgraduate teaching and placed on a formal basis. The faculty of the hospital's department of graduate medical instruction, which Dr. Snapper will head, consists of about 120 members of the Mount Sinai staff, many of whom are also members of the Columbia faculty. Dr. Baehr, under the new title of director of clinical research, will coordinate all the clinical research activities at the hospital, to gear them to the work of the laboratories and to bring about the most productive use of the institution's facilities. Dr. Baehr, until recently chief medical officer, U. S. Office of Civilian Defense, and formerly president of the hospital's medical board, has, in addition to the new position, returned to Mount Sinai as attending physician to the First Medical Service. Dr. Snapper, who formerly served on the faculties of the University of Amsterdam and the University of Peiping, has been appointed attending physician to the hospital's Second Medical Service. He was for nineteen years professor of propaedeutic medicine and general pathology at the University of Amsterdam. He later served as professor of medicine at the Peiping Union Medical College. After his arrest by the Japanese Army on Dec. 7, 1941 Dr. Snapper was later, in 1942, exchanged for five Japanese internees. In 1943 he went to the Netherlands West Indies on a special mission for the Netherlands government and later became consultant to the United States War Department, assigned to the office of the Surgeon General of the Army in Washington, D. C. He was also medical adviser to the commissioners of the Netherlands Indies, Surinam and Curaçao.

Bellevue Hospital Rapid Treatment Center Dedicated.—The dedication of the Bellevue Hospital rapid treatment center for controlling the spread of venereal diseases by the most advanced methods of therapy in syphilis and gonorrhea took place on April 1 with Mayor Fiorello H. LaGuardia giving the principal address. The center has been made possible through the cooperation of the Federal Works Agency and the U. S. Public Health Service. Lanham Act funds totaling

\$575,000 were allocated for the project. Federal maintenance will continue for the duration, but after the war the city department of hospitals will have the benefit of the construction and equipment, with the city providing funds for staff and maintenance. For syphilis the treatment will be in general arsenotherapy combined with fever. When and if penicillin is available, it will be used. For gonorrhea patients sulfonamide drugs will be used. Fever therapy will be used for those patients who do not respond to the sulfonamide drugs. The U. S. Public Health Service has assigned Cornelius T. Stepita, surgeon, U. S. P. H. S., as administrator of the treatment center under the direction of the medical superintendent of Bellevue Hospital, Dr. William F. Jacobs. The U. S. Public Health Service has also assigned a charge nurse and a record analyst. The maintenance and operation budget supplied through the Federal Works Agency provides for some 150 employees, including nurses, dietitians, medical social workers, educational and recreational staff, laboratory workers, hospital helpers, clerical staff and maintenance workers. Dr. Evan W. Thomas, chief syphilologist at Bellevue Hospital, and Dr. Alfred Cohn, in charge of gonococcus research for the department of health, will direct the treatment of patients, and all necessary medical, surgical and specialty consultations will be by the Bellevue Hospital visiting staff. There will be both an inpatient and an outpatient service at Bellevue which will have a 200 bed capacity. The building being utilized for the treatment center is the south wing of the six story pathology building, formerly used as a male dormitory for Bellevue Hospital employees. Reconstruction and remodeling work under the direction of the department of public works began last December. A rehabilitation program, to be conducted in buildings of the former Convalescent Day Camp on Welfare Island, is part of the rapid treatment center project. This will also be on twenty-four hour service with a 100 bed capacity and operated in conjunction with the board of education. The program will include vocational courses especially aimed at employment in war industries and recreational facilities for patients. After-care supervision will be the responsibility of medical social workers. Psychiatric service where necessary will be provided by Bellevue Hospital.

NORTH CAROLINA

Personal.—Fred W. Ellis, Ph.D., formerly associate in pharmacology at Jefferson Medical College of Philadelphia, has been appointed assistant professor of pharmacology in the University of North Carolina School of Medicine, Chapel Hill. —Dr. Frederick D. Austin Jr., Charlotte, coroner of Mecklenburg County, has entered military service.

Tri-State Meeting.—Dr. George H. Bunch, Columbia, S. C., was chosen president elect of the Tri-State Medical Association composed of North and South Carolina, Virginia, at its meeting in Charlotte, February 29, and Dr. Karl B. Pace, Greenville, was installed as president. Dr. Pace succeeds Dr. Frank S. Johns, Richmond, Va. Other officers include Dr. Oscar B. Darden, Richmond, and Richard B. Davis, Greensboro, vice presidents, and Dr. James M. Northington, Charlotte, secretary-treasurer. The association voted to hold its 1945 convention in Columbia.

OHIO

Selman Lecture.—Col. Richard P. Strong, director of tropical medicine, Army Medical School, Washington, D. C., delivered the Julius J. Selman Lecture at Mount Sinai Hospital, Cleveland, March 13, on "Tropical Diseases in Relation to the Present War."

Graduate Course.—The eighth annual graduate course in otology, rhinology and laryngology, University of Cincinnati College of Medicine, will be held May 15-20. This course is to be given by the department of otology and anatomy and is a refresher course for practicing otolaryngologists either in or out of the armed forces.

OREGON

Memorial Fund for Physician Who Died at Guadalcanal.—A memorial fund of \$600, contributed by friends of the late Lieut. Comdr. Joseph Lipschutz (MC), U. S. Naval Reserve, has been given to the University of Oregon Medical School, Portland, by his wife, Mrs. Ruth Lipschutz. Principal and interest of the fund will be used over a ten year period in granting awards to fourth year medical students writing the best essay in the field of pediatrics. The fund honors Dr. Lipschutz, formerly clinical instructor of pediatrics at the school, who met death while serving with the Navy in the Guadalcanal campaign.

PENNSYLVANIA

Course on Industrial Medicine.—The Lackawanna County Medical Society recently sponsored a course of ten sessions reviewing the subjects of industrial medicine and hygiene. The course was given under the direction of Lieut. Col. Arthur P. Hitchens, U. S. Army retired, George S. Pepper professor of preventive medicine and public health, University of Pennsylvania School of Medicine, Philadelphia. The program included speakers from the U. S. Public Health Service, including Medical Director Louis Schwartz, on "Occupational Dermatoses"; Principal Statistician William M. Gafafer, "Maintenance of Manpower," and Associate Statistician Hugh P. Brinton, "Women in Industry." In addition there were a number of speakers from various state departments in Pennsylvania.

Philadelphia

Dr. Landis to Lecture at Pennsylvania.—Dr. Eugene M. Landis, George Higginson professor of physiology at Harvard Medical School, Boston, will deliver the fourth annual Phi Delta Epsilon Honor Lecture at the University of Pennsylvania School of Medicine, April 14. His subject will be "A Comparison of the Clinical Tests of Kidney Function."

Course in Tropical Diseases.—The department of public health and preventive medicine, University of Pennsylvania School of Medicine, will inaugurate a Saturday afternoon course April 8 on epidemiology. Physicians and others interested may attend the course, which will place emphasis on the epidemiology of tropical diseases. *Philadelphia Medicine* reports that the tropical medicine section of the course is being organized so that the new sixth edition of the work on tropical diseases of Rear Admiral Edward R. Stitt, surgeon general, U. S. Navy, retired, prepared by Col. Richard P. Strong, M. C., A. U. S., will be used to guide and supplement the course.

Pittsburgh

Course in Tropical Diseases.—The committee on graduate education of the Allegheny County Medical Society is sponsoring a course on parasitology and tropical diseases for practicing physicians. The course will include a series of eight lectures to be given by Dr. Evelyn L. Heller, instructor in pathology, University of Pittsburgh School of Medicine. The lectures began April 5 and continue through May 24.

TEXAS

Council Created for Group Service Plan.—A new council on hospital service plans was recently organized in Texas to aid the expansion of group hospital service of Texas, to make recommendations relative to this work through the Texas Hospital Association, to advise with group hospital service and to coordinate the council activities with the administration of group hospital service. Mr. Lawrence Payne, superintendent of Baylor University Hospital, Dallas, is chairman.

University News.—The University of Texas Medical Branch, Galveston, has received a grant of \$2,400 from Frederick Stearns and Company, Detroit, to support a fellowship in pharmacology. A similar grant from the Bilhuber-Knoll Company of Orange, N. J., has also been given toward a fellowship in pharmacology. Recent appointments to the faculty of Baylor University College of Medicine, Houston, include John H. Perry, Ph.D., as assistant professor of anatomy, Dr. Paul A. Wheeler, associate professor of pathology, and Samuel Earl Kerr, lieutenant in the medical corps, Army of the United States, instructor in pathology.

UTAH

Dr. Ogilvie Resigns.—Dr. Orin A. Ogilvie has resigned as professor of bacteriology and pathology at the University of Utah School of Medicine, Salt Lake City, effective March 11.

VERMONT

University News.—A grant of \$1,500 has been made to Dr. Louis S. Goodman, professor of pharmacology and physiology at the University of Vermont College of Medicine, Burlington, by the Abbott Laboratories, North Chicago, Ill., for the study of synthetic anticonvulsants and analgesics. Corrine Manuel, B.S., M.T., has been appointed research assistant in the department of pharmacology and physiology.

VIRGINIA

Changes in Health Officers.—Dr. Thomas Scarlett, health officer of Harrisonburg, resigned, effective February 12, to enter military service.—Dr. Thomas F. McGough Jr., health officer of Pulaski-Wythe Health District, Pulaski, resigned effective February 16 to enter military service.—Dr. Daniel C. Steelsmith, health officer of Halifax-Pittsylvania Health District, South Boston, has resigned effective April 1.

WASHINGTON

New Director of Venereal Control.—Edwin N. Heschbacher, assistant surgeon, U. S. Public Health Service, has been appointed director of venereal disease control of the Seattle Health Department. He succeeds Dr. Burton L. Zinnamon, who has been transferred to Oakland, Calif.

City Creates Post of Municipal Psychologist.—The Seattle city council has been asked to establish a new municipal civil service position of psychologist to be used in connection with the treatment of women with venereal disease. According to *Northwest Medicine*, it was stated that the salary would be paid by the Federal Works Agency. Besides making a study of these patients, the psychologist would assist the social worker in placing them in industry.

Hospital News.—A gift of 81 acres in West Seattle by the King County commissioners to the federal government for the establishment of a veterans' hospital has been rejected because additional veterans construction in Washington is not under consideration.—The new Franklin D. Roosevelt Hospital, Bremerton, constructed at a cost of nearly \$1,000,000 from government funds, has been recently opened. It is county sponsored but will not be operated as a charity institution.

WEST VIRGINIA

Impostor Turns to Industrial Practice.—"Dr." Samuel Seymour Liebowitz, alias Charles Freeman Krueger, alias Samuel Seymour Strauss, has reappeared in West Virginia, seeking work as an assistant in industrial medical practice in the coal fields near Charleston. In his application, Liebowitz stated that he was a graduate of a foreign school, had taken his junior and senior years in medicine at the University of Pennsylvania and was licensed in Missouri and New York. He said further that he was a member of the staff of Spencer State Hospital (mental) at Spencer and that the public health council had given him a special permit to practice at that institution. An investigation by the West Virginia State Medical Association disclosed that no person by the name of Liebowitz had been connected with the Spencer institution and that no special permit to practice had been granted by the public health council to a doctor of that name. A physician at the coal fields ordered Liebowitz out of West Virginia. Liebowitz, on being advised to get out of the state, left the coal fields immediately but on March 21 turned up in Charleston on some trivial pretext in the offices of the state medical association. After considerable questioning, he admitted that he was "the same Liebowitz who 'practiced' in the coal fields of West Virginia in 1940 under the name of 'Dr. S. S. Strauss,' posing as a graduate of Long Island College of Medicine, Brooklyn, and as a regularly licensed physician in West Virginia. He also admitted that he had served time in the federal reformatory at Chillicothe, the Northwestern Penitentiary at Lewisburg, Pa., the U. S. Penitentiary at Atlanta and the U. S. Penitentiary at Terre Haute, Ind. The federal court records in West Virginia show that at the March 1941 term of the U. S. District Court for the northern district, at Parkersburg, Liebowitz was convicted on a charge of falsely and incorrectly registering for the draft and sentenced to serve two years at Atlanta. He states that he was later transferred to Terre Haute. He was paroled from the Terre Haute prison Oct. 26, 1942 and placed under the jurisdiction of the U. S. probation officer at South Bend, Ind. His conviction at Parkersburg in 1941 followed months of posing as a doctor and 'practicing' in various parts of the country, including relief work in many towns in the coal fields in West Virginia." A report of a thorough investigation by federal officers to the West Virginia State Medical Association revealed that Liebowitz had had no medical training whatever but had worked as an orderly in federal reformatory hospitals. "Liebowitz, while freely admitting the truth of most of the evidence with which he was confronted, stoutly maintained that he is a graduate of the 'University of Vienna,' class of 1939, and that he had interned at 'Westminster Hospital, London,' in 1940, coming to the United States in March 1940. He stated that he had had several jobs since his parole from Terre Haute, working in Whiting, Ind., and at Louisville, Ky. He said he came back to West Virginia because he had no work and because he is 'qualified to practice medicine in the coal fields.'" At the time of his visit to the offices of the state medical association he was advised to leave West Virginia without delay. Exhibiting a bus ticket, he stated he had decided to get work on a farm and was leaving that afternoon for Philadelphia. Members of the medical profession in West Virginia are requested to watch for "Dr." Liebowitz and to notify Dr. John E. Offner, state health commissioner and secretary of the public health council, if he should turn up in their community. Liebowitz first appeared at the headquarters of the

state medical association in 1940, giving his name as S. S. Strauss and saying that he was a graduate of the Long Island College of Medicine and that he was licensed to practice in West Virginia. He obtained positions doing relief work in various towns in the coal fields but disappeared when it became known that he was not licensed and had not graduated from the Long Island College. In Kingwood, state police took him in custody as a suspicious character and discovered that, while his automobile license was in the name of Samuel Strauss, his draft registration card bore the name Kreiger. The police notified the U. S. Department of Justice, which sent back a police record dating from 1933. He has used various aliases, including Seymour Rothchild, Seymour Davis Strauss, Milton Fenberg, Seymour Strauss, Samuel Liebowitz and Samuel Seymour Strauss. His activities had been carried on in a number of states and his sentences included terms in various penal institutions for using the mails to defraud and one for vagrancy.

GENERAL

Society News.—The American Association for the Advancement of Science will hold its 111th annual meeting in Cleveland, September 11-16.

Cumulative Index of Radiology.—The Radiological Society of North America has just issued a cumulative index of its official publication, *Radiology*, covering the years 1923-1942, volumes 1-39. In the organization of the index the *Quarterly Cumulative Index Medicus*, published by the American Medical Association, has been used as a pattern.

Orthoptic Examinations.—The American Orthoptic Council announces that applications for the next examinations must be received before August 1. The written examinations will be held in various cities throughout the country on September 7. Only those passing the written examinations will be permitted to take the oral and practical tests, to be given in Chicago on October 7. The address of the council is 23 East 79th Street, New York 21.

New Managing Director for Society for the Hard of Hearing.—Mr. Raymond H. Greenman, formerly executive secretary of the Tuberculosis and Health Association of Rochester and Monroe County, New York, has left a war assignment with the American Social Hygiene Association to become managing director of the American Society for the Hard of Hearing, Washington, D. C. Mr. Greenman succeeds Miss Betty C. Wright, who is on a three months leave of absence from the society to serve with the American Red Cross as consultant in three army hospitals for the special care of deafened soldiers. Miss Wright will return to the society in August as director of field service. The society also announces that it is embarking on a war activity aimed to meet, through the cooperation of its 121 local chapters, the rehabilitation needs of the war deafened soldiers. The society will observe its twenty-fifth anniversary this year.

Tropical Medicine News.—The first issue of *Tropical Medicine News*, published by the American Society of Tropical Medicine, made its appearance with the February issue. The bulletin is aimed to keep members in touch with happenings within the society and will appear bimonthly during the months when the *American Journal of Tropical Medicine*, the official organ of the society, also a bimonthly publication, is not published. The *News* has been so planned that it will be self supporting as the result of pharmaceutical advertising. The notices of three firms are to appear in alternating position on the back cover and the inside cover pages of each issue. The space for the six issues of 1944 has been purchased by Eli Lilly & Company, G. D. Searle & Company and John Wyeth & Brother, Inc. The cover of the *News* is the work of the art department of Tulane University of Louisiana School of Medicine, New Orleans, and has been adopted from the seal of the society. The seal itself depicts a seated Roman goddess, in a tropical setting, who extends the lamp of knowledge to the serpent, the symbol of healing. The anopheline mosquito, the scorpion and the leaves and open flower of *Cinchona ledgeriana* have been added at the base of the seal, and the motto of the society, *Salus in Tropica*, has been retained. The first issue contains a report of the 1943 meeting of the society, clinical and research notes, news items and a list of the officers.

LATIN AMERICA

Health Activities in Latin America.—*Brazil Supervises Penicillin Manufacture.*—The manufacture of penicillin was placed under government supervision and its export was prohibited on March 8 by President Getulio Vargas, the *New York Times* reported. It was stated that a few days before a large consignment was found at Rio Grande do Sul on an airplane bound for Argentina. Recently Brazil sent penicillin

to Spain, the United States and Great Britain. The drug is produced in both Rio de Janeiro and São Paulo states. On March 8 the government also voted \$200,000 to increase production.

Society News.—New officers of the Sociedad Cubana de Urología include Drs. José A. Hernández, Ibañez, president; Luis F. Ajamil, vice president; Ramiro de la Riva and Luis Hernández Hernández, secretaries, and Ernesto Puget and Gabriel Vandama, treasurers.

Assistance in Venereal Care.—On March 14 the executive council of Puerto Rico adopted a resolution accepting the offer of the United States of America to contribute to the people of Puerto Rico (\$167,632) for the maintenance and operation of venereal disease hospital facilities at Cayey, Maricao, Caguas and Finca Troche. The gift will extend through June 30.

Personal.—Lieut. Col. Edgar Tostes, Panair do Brasil, head of the Aeronautical Hospital, Brazil, was recently awarded the diploma of honor of the Association of Military Surgeons of the United States in recognition of his "outstanding contribution to military medical care in the Western Hemisphere," according to an announcement from the Pan American Airways System.

FOREIGN

Personal.—On January 13 Sir Henry H. Dale, president of the Royal Society and director of the laboratories of the Royal Institution, London, was presented with the Hanbury Memorial Medal of the British Pharmaceutical Society. The honorary gold medal of the Royal College of Surgeons, London, was presented at the Buckston Browne luncheon at the college on February 12 to W. H. Collins, chairman of King Edward VII Hospital, Windsor, in recognition of his gift of £100,000 (*THE JOURNAL*, Nov. 27, 1943, p. 851) to endow the department of pathology, with provision for a further like sum to extend and develop the department of pathology at Lincoln's Inn Fields and to found there a chair of human and comparative pathology. The Rockefeller Foundation has made an appropriation of £1,200 for biochemical investigations of penicillin under the direction of Howard Walter Florey Ph.D., professor of pathology at the University of Oxford.

King's Physician Terms Health Plan "Despotism."—The King's physician, Viscount Dawson of Penn, asserted in the House of Lords, London, that "signs of the new despotism" were in the White Paper outlining the health scheme recently presented to Parliament (*THE JOURNAL*, March 18, p. 789). According to the *New York Times* the debate in the two houses of Parliament was initiated on motions indicating the government's intention to establish a comprehensive health program. The purpose of the debate, it was stated, was to obtain criticisms of the plan before drafting a bill to effectuate it. The *Times* stated that criticisms came in a downpour, especially from some of the eighteen doctors in the two houses. The suggestion was made that the doctors would be assigned "beats like a policeman or a postman and paid like schoolmasters." In the House of Commons, the *Times* continued, Minister of Health Henry U. Willink commenced discussion with a conciliatory speech aimed at placating those doctors who regard the plan as a threat to their independence. "No one, patient or doctor, must be dragooned into any part of this service," Mr. Willink said. He assured the House that the government did not intend to regiment doctors, prohibit private practice or eliminate voluntary hospitals—that is, hospitals supported by public contributions. The doctors disagreed violently in the ensuing argument, it was stated. Sir Ernest G. Graham-Little, internationally known skin specialist, asserted, despite a tart challenge from Dr. Edith C. Summerskill, vice president of the Socialist Medical Association, that the "vast majority" of doctors who must operate the scheme would be "intensely resentful of the conditions imposed on them." Dr. Leslie Haden Guest, demanding removal of commercialism from the profession, also denied Sir Ernest's claim to represent a large part of the medical profession, and Mr. Alexander G. Walkden said to Mr. Willink "Young doctors welcome your scheme." Replying to a government statement by Lord Woolton, minister of reconstruction, Lord Dawson criticized the way in which the White Paper seemed to introduce a salaried service for doctors and said that civil service control would mean "goodbye to the best that medicine can do." Mr. Willink described the plan as the "biggest single advance ever made in this country in the sphere of public health"—a scheme to make the whole range of health care available to every person, the cost to be shared by the beneficiaries and the taxpayers.

Foreign Letters

LONDON

(From Our Regular Correspondent)

March 4, 1944.

The Medical Press and the National Health Service

A qualified welcome is given by the *British Medical Journal* to the government plan for a national health service. The recent white paper on this subject is characterized by the *British Medical Journal* as well written and for the most part unambiguous. For the moment, those who are opposed to a whole time salaried state medical service have had their fears allayed. But the suggestion that a central medical board should have power to prevent doctors from entering an "overdoctored" area and that no one should practice anywhere without first obtaining permission of the board, a civil service structure, is held to be more than a hint of authoritarianism. The white paper states that "the board must be able to require the young doctor during the early years of his career to give his full time to the public service where the needs of the service require this." This seems to conflict with the principle of "no compulsion into the new service of either patient or doctor." The *British Medical Journal* sees in the white paper the unmistakable direction in which the government is moving—toward the institution of a whole time salaried service, with the proviso that private practice shall not be denied to those who want it and that doctors in the public service may provide it. "It is difficult to see how, in the kind of evolutionary changes which are so persuasively outlined, private practice as we know it today can survive much more than as a shadow of itself. Our contemporary detects a thread of argument and development leading in a direction which the profession refuses and will refuse to follow—that of whole time salaried service under the state," it is declared.

The *Lancet* also welcomes the white paper and characterizes the scheme as "bold as well as reasonable." It holds that "within the framework suggested it would be possible soon to increase the value of medical knowledge to the public, to give most doctors more satisfaction in their work, and in doing so to prepare the way for a really fine service in the years to come." The new service must set itself from the first to make more economical use of the doctors available, the *Lancet* says. This, it is held, can be achieved only by rapid development of the health centers, which would do something to conserve the doctor's time and energy.

New Cooperative Program of British Empire Cancer Campaign

One of the most important duties of the British Empire Cancer Campaign has been to review new suggestions as to the cause and treatment of cancer. In the past, the conclusions formed have not always reached the medical profession. The campaign has now expressed its willingness to give its opinion on any new form of treatment on which it has information. It will continue to investigate methods of treatment and theories of causation and is willing to undertake or promote research into these, provided the following conditions are fulfilled: 1. That in the opinion of the appropriate expert committee of the campaign the subject offers any prospect of advancing the solution of the cancer problem. 2. That the fact that a theory or suggested treatment is being investigated by the British Empire Cancer Campaign shall be disclosed only with the consent of the campaign. This condition seems to be laid down to prevent exploitation of the fact that an alleged remedy is being investigated by the campaign. 3. That the campaign reserves

to itself the right to publish in an appropriate manner the conclusions reached, whether favorable or unfavorable. 4. That in the case of theories concerning causation all available information shall be furnished by the advocate of the theory on the scientific basis and the experimental data, which shall be so detailed that exact repetition of the experiments can be carried out by experts in the field concerned. 5. That in the case of methods of treatment the precise nature, composition and method of administration shall be disclosed and the evidence shall be collected in accordance with safeguards as to scientific accuracy which experience has shown to be essential, namely (a) that cases shall be of proved cancer as far as proof is practicable, preferably by microscopic examination (if possible also they should be cases affecting accessible organs such as the skin, breast, cervix uteri and mouth), (b) that every case treated shall be recorded whether the result is favorable or otherwise, and (c) that clinical records, including follow-up, shall be as full as possible. 6. That in the case of treatment based on experiments the campaign reserves to itself the right to confirm the results of such experiments before attempting clinical trials of the remedy. The campaign also announces that it will be happy to arrange for physicians to discuss their hypotheses and experiences with appropriate experts. The address of the campaign offices is 11 Grosvenor Crescent, London S.W. 1.

Special Investigation of Diseases and Care of the Aged

Two important changes are evident in the British population: a fall in its rate of increase, with a decrease imminent, and an increase in the average length of life. At the beginning of the century 2,250,000, or 1 in 17 of the population, were of pensionable age (65 for men and 60 for women). By 1941 this figure had risen to 5,500,000, and it is calculated that by 1961 it will be over 8,000,000, or 1 in 6 of the population. These facts provide a serious problem for our public health authorities in their care of the aged. The Nuffield Foundation trustees are undertaking a survey of the problems of aging and the care of old persons. The Ministry of Health has warmly welcomed the proposal and will cooperate. The object of the survey is to collect and collate information on (1) the problems, individual, social and medical, associated with aging and old age, (2) the work being done by public authorities and voluntary organizations and the public and private resources that exist for the care and comfort of the old, (3) the provision made for old persons in other countries which have given special consideration to the problem, (4) medical research on the causes and results of aging and (5) the lines on which action might be usefully taken in the future by public authorities and private organizations, including the Nuffield Foundation. Questions of medical research will be considered by a special subcommittee of leading physicians.

It is remarkable that while the diseases of children have, rightly, received a great deal of attention, those of persons at the other end of life have not been similarly investigated. Much of course is known about the pathologic changes in the aged, but the trustees hold that in questions of aging and the care of the aged there is lack of collated information of a comprehensive and authoritative nature. This militates against proper appreciation of the problems involved and hinders the search for adequate solutions. The survey now undertaken should lead to an important contribution to better understanding of a social problem which will inevitably occupy an increasingly important place in public thought and policy. It will also provide the Nuffield Foundation with a proper basis on which to decide its future action with regard to the care of old persons. The present population trend has already influenced mortality statistics. Certain diseases of the elderly, such as cancer, already show an absolute increase in number.

A Modern Hospital and Medical School for Ethiopia

During the years 1936 to 1941, when Italy exerted an uneasy rule over Ethiopia, the emperor lived in England. His daughter, Princess Tsahai, undertook training as a nurse at our principal children's hospital, the Hospital for Sick Children, on Great Ormond Street. After passing the examinations qualifying her as a nurse, she entered Guy's Hospital for further training. Her object was to fit herself to lead a movement for establishing a modern nursing service in Ethiopia when its freedom was regained. But, unfortunately, she died in 1942, at the age of 22. An appeal is now being made for funds to found in Ethiopia a modern hospital and medical school in her memory as a token of good will from the people of Britain. The appeal is supported by the leaders of the medical and nursing professions.

BRAZIL

(From Our Regular Correspondent)

Feb. 20, 1944.

Low Cost Collective Feeding

As a result principally of continued effort by modern physicians in Brazil, the eating habits of the population are being changed for the better; old, unbalanced and incomplete diets are being abandoned and new customs are being created, especially among the higher classes. This was and still is a recognized necessity, because the Brazilian common diet is, as a rule, defective, monotonous and insufficient for the active life that a large part of the population is now beginning to adopt. Some aspects of this problem may be grasped from a paper that has just been published by Drs. Olavo Rocha and J. Fleiuss, in which they describe their work to organize, on a modern basis, the furnishing of more than a million meals to some 2,000 workers at the Fabrica Nacional de Motores, the Brazilian national airplane motor factory located in a distant suburb of the city of Rio de Janeiro. The cost of the meals is considered rather low (roughly corresponding to 10 cents per meal), if present war conditions are taken into consideration. The task of furnishing the meals had been previously given to a nutrition and social welfare organization which is pioneering in the difficult field of furnishing low cost, collective feeding of proper quality. The meals were sent to the factory in thermal trucks. Despite the fact that the food supplied was prepared with the best quality of foodstuffs and had excellent appearance, quite unexpectedly at the end of about a month the workers and even the administrative staff of the factory began to complain about the food, showing some degree of aversion toward it. Some of the results of the study made by Drs. Rocha and Fleiuss of the causes of this intolerance and the measures taken to correct them are summarized here.

The so-called rational diets of the welfare organization were generally based on calory calculations and on the minimum protein, vitamin and mineral salt content, little emphasis being put on the taste and variety of the foods. In the effort to organize scientific and balanced diets, the menus departed too far from the eating habits of Brazilian workers, it was found, and were typically monotonous. The authors convinced the management of the factory that the meals should be prepared at its site. Within the list of foods most readily found in the market and most commonly in use, they planned a great variety of menus. They recognized the fundamental importance, in collective feeding, of the taste of the food, which in large part depends on flavoring and seasoning, a factor which plays a prominent part in the digestibility of the food. The authors suggested that the flavoring might not be limited to the habitual seasonings—salt, vinegar, garlic, onion, tomato and tomato catsup—used in the dishes furnished by the organization. They proposed to increase the amounts of these seasonings four and five times. In the food prepared at the factory, these seasoning agents have

reached the daily amounts per person of garlic 1 Gm., onion 10 Gm., tomato 8 Gm. and vinegar 5.5 cc. They suggested further that other flavorings, like laurel leaves, parsley, pimento and annato seeds (*Bixa orellana*), be used. It is to be noted that this practice did not materially increase the number of digestive disturbances. The only important reactions were registered in connection with a small number of workers presenting some kind of allergy or with organic lesions of the digestive or circulatory systems (hyperchlorhydria with or without peptic ulcers, biliary troubles, chronic colitis [mainly amebic] and hypertension with some degree of nitrogen retention).

All the meals furnished by the social welfare organization included a glass of milk, which the workers were not accustomed to take at lunch and dinner time. Most of the workers do not like to take milk at all; they even regard it with aversion, saying that it is "a food for sick men, for weak men, for frail girls, for women in childbed" and not suitable for "full grown men, strong men, men who have to do hard work." But as a result of this educational effort the workers are being trained to take milk with the morning coffee.

The authors state that the correction of the monotony of the diet and the increase in the seasoning of the dishes have accounted for a decided improvement in the acceptance of the food. Thus adequate amounts of food are now enjoyed, as well as proper quality, a fact that is a feature of the present system of feeding workers at the factory.

The Death of Fernando Magalhães

Dr. Fernando Magalhães, professor of obstetrics at the University of Rio de Janeiro, died a few days ago at the age of 64. He was one of the leading medical men of Brazil and was considered the pioneer of modern obstetrics in this country. He was still young when he took the full professorship of obstetrics at the university, after a competitive selection which aroused great interest in medical circles at the time. He was also elected a member of the Brazilian Academy of Medicine, the highest professional association, constituted, as a rule, by the elder representatives of the principal medical specialties in the country. He was actually a reformer of obstetrics in Brazil, not only by his teaching in the principal medical school of the country but, mainly, as the leader of a campaign to introduce the use of the best technic in his specialty. The modern treatment of puerperal sepsis, the use of cesarean section when necessary, the problem of painless childbirth, the right conduct in case of placenta previa, cancer of the uterus, correct forceps technic—these are some of the problems to which he devoted his best efforts. He was an open minded physician and a courageous fighter for his professional ideals. In 1918 he founded the Pro-Matre Hospital, a modern private maternity hospital where he had the best field for his studies and teachings and where many leading obstetricians of the present time began their careers. One of his students, Dr. C. Correa da Costa, is now director of the Arthur Bernardes Maternity, where he has achieved spectacular results in the control of puerperal sepsis by applying the principles taught by Dr. Magalhães.

Marriages

WILLIAM R. DANDRIDGE, Charlottesville, Va., to Miss Hetty Wray Hurd of Martinsville in Strasburg, March 3.

OLIVER BRYSON WINGO to Miss Dorothy Bartlett, both of Birmingham, Ala., in Scottsboro recently.

CHARLES L. BENSON, Tamaqua, Pa., to Miss Marjorie J. Duffy of East Mauch Chunk, January 1.

EARL L. LOYD, Salina, Kan., to Miss Margaret Elizabeth Stevens of Minneapolis in February.

Deaths

Robert Anthony Hatcher Ⓢ Flushing, N. Y., noted pharmacologist, died April 1 of angina pectoris, aged 76.

Dr. Hatcher was born in New Madrid, Mo., Feb. 6, 1868. He received his Ph.G. at the Philadelphia College of Pharmacy in 1889, graduating at Tulane University of Louisiana School of Medicine, New Orleans, in 1898. Honorary degrees that were later conferred on him included the master in pharmacy from his alma mater and a doctor of science in pharmacy from Columbia University. He was professor of materia medica at the Cleveland School of Pharmacy, 1899-1904, and demonstrator of pharmacology at Western Reserve University School of Medicine, Cleveland, 1901-1903. He went to Cornell University Medical College as instructor in pharmacology in 1904; he was assistant professor of pharmacology and materia medica there from 1906 to 1908 and professor from 1908 until 1935, when he became professor emeritus.

At the time of his death Dr. Hatcher was one of the few remaining charter members of the Council on Pharmacy and Chemistry of the American Medical Association. He had served continuously as a member of the Council since 1905, when it was created. In 1943, when he retired at the age of 75, the Board of Trustees of the American Medical Association made him an honorary life member, the first member of the Council ever to receive this recognition. He was chairman of the Section on Pharmacology and Therapeutics of the American Medical Association from 1915 to 1916 and a member of the House of Delegates of the Association in 1917.

Dr. Hatcher was a recognized authority on digitalis. Much of the success of the Council on Pharmacy and Chemistry is attributed to his efforts. Up until the time of his retirement in 1943 he was constantly busy with the preparation and editing of reports, retaining the interest that had made him an able influence in the development of the Council.

His contributions in the field of research and education are widely known. Dr. Hatcher was a member of a number of scientific groups including the American Association for the Advancement of Science, the American Pharmaceutical Association, the American Physiological Society, the American Society of Biological Chemists, American Society for Pharmacology and Experimental Therapeutics and the Harvey Society. Included among his many writings were the "Textbook of Materia Medica," of which Dr. Torald H. Sollmann was co-author, 1904, and "Pharmacology of Useful Drugs" (with M. I. Wilbert) 1915. He served for a time as editor of Useful Drugs.

Morris Manges Ⓢ New York; College of Physicians and Surgeons, New York, 1887; member of the American Climatological Association, New York Pathological Society, American Gastro-Enterological Association, Harvey Society, American Association for the Advancement of Science, Archeological Institute of America and Oriental Institute of the University of Chicago; fellow of the New York Academy of Medicine; professor of clinical medicine at the New York Polyclinic Medical School and Hospital from 1898 to 1908 and for many years clinical professor of medicine at the University and Bellevue Hospital Medical College; served on the staff of the Mount Sinai Hospital; formerly consulting physician to Hospital for Joint Diseases, and Hebrew Orphan Asylum; editor of "Ewald's Diseases of the Stomach" in 1892 and 1896; died January 26, aged 78, of coronary thrombosis.

Hugh White Priddy, Memphis, Tenn.; University of Tennessee College of Medicine, Memphis, 1915; member of the Tennessee State Medical Association; member and in 1939 vice president of the Southern Psychiatric Association; president of the Memphis Hospital Association in 1933; formerly assistant in medicine, neurology and psychiatry and instructor in neurology and psychiatry at his alma mater; served as a lieutenant during World War I; at one time part owner of the Leigh and Priddy Hospital, Charleston, Miss., and the Wallace Sanitarium; served on the staffs of the Memphis General and Baptist Memorial hospitals and the Home for Incurables; member of the Memphis Rotary Club; died January 17, aged 56, of myocardial insufficiency.

Charles Allen Riley Ⓢ Boston; Jefferson Medical College of Philadelphia, 1905; assistant in pulmonary diseases from 1910 to 1916, instructor, pulmonary diseases from 1916 to 1925, instructor, pulmonary diseases and climatology from 1925 to 1929 and instructor in medicine from 1932 to 1934 at Tufts College Medical School; captain in the medical corps of the U. S. Army during World War I; on the active staff of the health department of Boston and consultant for the health department of Newton; on the staffs of the Boston Dispensary and Boston Sanatorium; on the staff of the Brooks Hospital, Brookline; died January 30, aged 62, of coronary thrombosis.

Oliver S. Bacon, St. Louis; Missouri Medical College, St. Louis, 1889; died in Maplewood, Mo., January 19, aged 79, of chronic endocarditis.

Milton Reed Barker, Wilmette, Ill.; Chicago Homeopathic Medical College, 1890; Northwestern University Medical School, Chicago, 1901; for many years on the staff of St. Francis Hospital, Evanston; died February 3, aged 92, of coronary thrombosis and endocarditis.

John Henry Richard Barry, Forest Hills, N. Y.; College of Physicians and Surgeons, New York, 1890; member of the Medical Society of the State of New York; past president of the Queens-Nassau Medical Society; in 1938 retired after thirty years as assistant sanitary superintendent department of health for the borough of Queens; served on the staff of St. John's Long Island City Hospital, where he died March 10, aged 75, of angina pectoris.

Edgar Bates, Ogden, Utah; University of Michigan De-

partment of Medicine and Surgery, Ann Arbor, 1900; formerly associated with the Indian Service at Warm Springs, Ore.; died January 24, aged 74, of complications following a fall, and senility.

Galen Sibley Battey, Cawker City, Kan.; the Hahnemann Medical College and Hospital, Chicago, 1880; died January 21, aged 88, of cerebral hemorrhage.

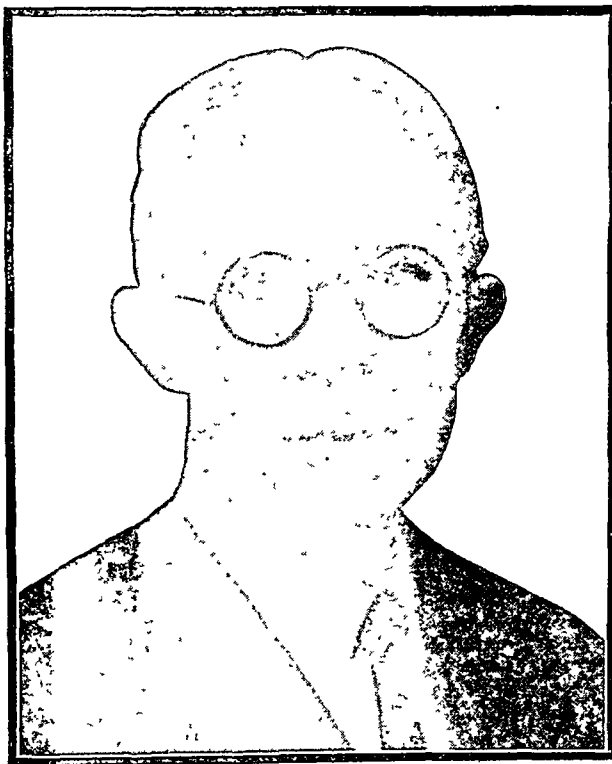

George Andrews Cooke, Boston; Long Island College Hospital, Brooklyn, 1891; school physician of Montague, Mass., for many years; cofounder of the Franklin County Public Hospital, Greenfield; died recently, aged 77, of heart disease.

Morris W. Cowden, Gerry, N. Y.; University of Buffalo School of Medicine, 1890; for more than fifty years health officer of the town of Gerry; died January 24, aged 82, of chronic myocarditis and arteriosclerosis.

Aloysius Francis Dowd, Boston; Tufts College Medical School, Boston, 1919; died recently, aged 48.

Walter L. Gaines, Wheeler, Texas (licensed in Texas under the Act of 1907); died in a hospital at Spur, January 6, aged 67.

Ernest H. Gibbs Ⓢ Pittsburgh; Detroit College of Medicine, 1910; died in the Presbyterian Hospital January 11, aged 55, of congestive heart disease.

ROBERT ANTHONY HATCHER, M.D., 1868-1944

J. A. M. A.
April 8, 1944

Albert Donne Gibson, Port Lavaca, Texas; Wisconsin College of Physicians and Surgeons, Milwaukee, 1897; member of the State Medical Association of Texas; served as city health officer and as acting assistant surgeon in the U. S. Public Health Service; died in the De Tar Memorial Hospital, Victoria, January 6, aged 69, of uremia.

Ernest Reed Hirst ♂ Camden, N. J.; Jefferson Medical College of Philadelphia, 1918; member of the American Academy of Ophthalmology and Otolaryngology; specialist certified by the American Board of Otolaryngology; on the staffs of the Zuerhugg Memorial Hospital, Riverside, and the Cooper Hospital, where he died January 27, aged 51, of coronary thrombosis.

George Hofstetter ♂ Clinton, Iowa; Rush Medical College, Chicago, 1882; an Affiliate Fellow of the American Medical Association; on the staffs of the St. Joseph, Mercy and the Jane Lamb Memorial hospitals; died January 28, aged 86, of paralysis agitans.

Lydia Heckman Holmes, Pekin, Ill.; Loyola University School of Medicine, Chicago, 1917; member of the Illinois State Medical Society; past president and vice president of the Tazewell County Medical Society; at one time medical director and superintendent of the Fairview Sanatorium (McLean County Tuberculosis Sanatorium), Normal; on the staff of the Pekin Public Hospital, where she died January 22, aged 72, of diabetes mellitus.

John Robert Hood, Indianahoma, Okla.; Hospital College of Medicine, Louisville, Ky., 1897; died in Lawton January 18, aged 74, of vascular degeneration and renal disease.

Arthur Ernest Jessup, Diagonal, Iowa; State University of Iowa College of Medicine, Iowa City, 1895; member of the Iowa State Medical Society; died January 12, aged 74, of cardiorenal disease.

Horace G. Lamb, Santa Rosa, Calif.; California Medical College, San Francisco, 1901; died January 20, aged 83.

Richard Percy Landis, Vallejo, Calif.; University of Oregon Medical School, Portland, 1918; served during World War I; at one time owner of the Landis Clinic and Hospital, Grass Valley; died in the Vallejo General Hospital January 24, aged 54, of cerebral hemorrhage.

Clyde Raymond Larkins ♂ East Liverpool, Ohio; Jefferson Medical College of Philadelphia, 1903; president of the board of trustees and member of the staff, East Liverpool City Hospital; died January 29, aged 68, of heart disease.

Waldo Nathaniel Lemmon, Hereford, Texas; Barnes Medical College, St. Louis, 1899; member of the State Medical Association of Texas; also a minister; at one time a medical missionary in the Philippine Islands; past president of the Meade-Seward Counties (Kan.) Medical Society and the Randall-Deaf Smith-Parmer-Castro-Oldham Counties Medical Society; on the staff of the Deaf Smith County Hospital, where he died January 1, aged 71.

Andrew De Witt Mahaffay, San Juan, Texas; Hahnemann Medical College of the Kansas City University, Kansas City, Mo., 1902; member of the chamber of commerce; died January 12, aged 78, of injuries received in an automobile accident.

George Robert Mankis, Providence, R. I.; Hahnemann Medical College and Hospital of Philadelphia, 1932; on the staffs of the Homeopathic Hospital and St. Joseph's Hospital, where he died January 23, aged 37, of cerebral hemorrhage.

Thomas Gordon McCleary, Excelsior Springs, Mo.; Hahnemann Medical College and Hospital of Philadelphia, 1921; died January 9, aged 46, of brain tumor.

John E. Meany, Manitowoc, Wis.; Milwaukee Medical College, 1898; honorary life member of the State Medical Society of Wisconsin; past president and secretary of the Manitowoc County Medical Society; formerly city health officer; served on the staff of the Holy Family Hospital, where he died January 19, aged 81, of general carcinoma.

Albert J. Muckerheide, Milwaukee; Milwaukee Medical College, 1900; member of the State Medical Society of Wisconsin; died January 24, aged 69, of cerebral hemorrhage.

Ralph Edgar Niedringhaus ♂ St. Louis; St. Louis College of Physicians and Surgeons, 1898; served as a captain in the medical corps, U. S. Army, during World War I; at one time a member of the Illinois State Board of Health; died January 19, aged 66, of carcinoma of the cecum and cerebral arteriosclerosis.

Maud Parker, Seattle; Cornell University Medical College, New York, 1905; member of the Washington State Medical Association; served as a member of the board of trustees of the King County Medical Society and as secretary of the Medical Women's National Association; formerly on the staffs of the Seattle General and Swedish hospitals; died January 16, aged 66, of tuberculosis.

Walter Andrew Poche, Kaplan, La.; Medical Department of Tulane University of Louisiana, New Orleans, 1902; died in Our Lady of the Lake Sanitarium, Baton Rouge, recently, aged 68, of coronary occlusion.

Leonard Holden Pote, Somerville, Mass.; Harvard Medical School, Boston, 1900; member of the Massachusetts Medical Society; died in Boston recently, aged 69, of carcinoma of the prostate.

James Frederick Roach, Centralia, Ill.; Missouri Medical College, St. Louis, 1896; served during World War I in France and later in Siberia; at one time affiliated with U. S. Veterans Bureau and the U. S. Public Health Service; died in West Palm Beach, Fla., January 26, aged 69, of diabetes mellitus and heart disease.

Maurice S. Schimmel ♂ Baltimore; Baltimore University School of Medicine, 1895; died in the Sinai Hospital January 12, aged 74, of bronchopneumonia and carcinoma of the liver.

Ivan W. Staples, Norway, Maine; Medical School of Maine, Portland, 1909; member of the Maine Medical Association; at one time examiner for the U. S. Pension Board; died recently, aged 60, of angina pectoris.

William D. Townley, Chamois, Mo.; Missouri Medical College, St. Louis, 1882; died in St. Mary's Hospital, Jefferson City, January 26, aged 84, of heart disease.

Isaac Johnson Townes ♂ Madisonville, Ky.; Jefferson Medical College of Philadelphia, 1889; vice president of the Hopkins County Medical Society; died in Mayfield January 22, aged 76, of coronary thrombosis.

Harwood Vernon, Verona, N. J.; University of Vermont College of Medicine, Burlington, 1895; died January 17, aged 75, of arteriosclerotic heart disease.

Redone Edgar Wasson, Fairview, Ill.; Keokuk (Iowa) Medical College, College of Physicians and Surgeons, 1906; member of the Illinois State Medical Society; director of the Fairview State Bank; died in the Graham Hospital, Canton, January 22, aged 78.

Harry J. Wertman ♂ Milford, Neb.; Rush Medical College, Chicago, 1903; for many years member and chairman of the board of education; served as a member of the fire department; died in Alhambra, Calif., January 26, aged 66, of cerebral hemorrhage and arteriosclerosis.

Leo Sheldon Wright, Lowry City, Mo.; University Medical College of Kansas City, Mo., 1899; died January 23, aged 66.

Hyman Yudin, Beverly, Mass.; College of Physicians and Surgeons, Boston, 1918; member of the Massachusetts Medical Society; died recently, aged 53.

KILLED IN ACTION

Ward Robert Vincent, Ventura, Calif.; Harvard Medical School, Boston, 1939; formerly a resident physician on the staff of the Ventura County Hospital; commissioned a lieutenant (jg), medical corps, U. S. Naval Reserve, March 7, 1942; later promoted to lieutenant; killed in the Pacific theater Nov. 20, 1943, aged 29.

LIEUT. WARD R. VINCENT (MC),
U.S.N.R., 1914-1943

Bureau of Investigation

SOME MISCELLANEOUS MEDICAL FRAUDS

A Variety of Schemes Debarred from the Mails

Fraud orders issued by the Post Office Department have frequently been the subject of extensive articles by the Bureau of Investigation in these pages of THE JOURNAL. Following are abstracts of some fraud orders not dealt with previously.

"Dr." Clarence O R Rodney—For a mere 25 cent coin, this Chicagoan gave advice on how to remove a "junk," correct an unhappy marriage, conduct love affairs, have children, make money, or cure gambling or drinking habits. When the Post Office Department investigated Rodney's operations, it learned that he was a registered alien who came to this country from British Guiana in 1933, opened his small Chicago office in June 1940 and began doing business through the mails about a year later, advertising mostly in Negro newspapers. He referred to himself as "Doctor" and "psychologist," claiming to have received the degree of 'Doctor of Psychology (P.S.D.)' from 'The College of Divine Meta physics' at Indianapolis. The Post Office Department ordered him to show cause on Jan 21, 1943, at Washington, why a fraud order should not be issued against him. At the hearing Rodney was represented by a Chicago attorney. It was charged that Rodney was conducting a fraudulent mail order scheme, in that he represented himself as a bona fide physician, sold advice on personal problems relating to money, love, marriage, sickness and some other things, and furnished a horoscope of each remitter, that the "answers" which Rodney sent his customers were not applicable to their particular ailments or individual problems, but were merely mimeographed or carbon copies of vague and incoherent form letters used by Rodney, and that he sometimes asked for additional fees. It was shown further that Rodney offered "Scientific and Dynamic Help through the process of Telepathic and Clairvoyant Working Operations" to enable the customer to throw off "abnormalities" and also sent him a booklet entitled 'The Secret of Prosperity, Success and Happiness.' Rodney issued alleged psychologic "prescriptions" which, the government charged, contained some preposterous advice. Since no evidence was presented on behalf of Rodney in defense of the charges, and since he was found to be falsely representing himself as a physician and using the mails to swindle the ignorant, his business was debarred from the mails by a Post Office fraud order issued on April 23, 1943.

Lyncha A Johnson—This person did business from Memphis, Tenn., as "Dr. Lyncha A Johnson, Master Herbalist and Dr. of Naturopathy." His advertising referred to his business as a 'Botanic Drug Store and Herbal Health Home' where he had "Thousands of Nature's Wonderful Plants for Suffering Humanity." As a result of complaints sent by 5 of his victims, the Post Office Department investigated, and a hearing of the case was held in Washington on Jan 28, 1943, at which Johnson was present with his counsel. A microanalytically testified for the government that one Johnson nostrum, "Formula No 5x55," was essentially a mixture of podophyllin, belladonna, ginger, aloin and possibly cascara, and that another, "Compound Herb Tea No 4," contained coarsely ground herbs including equisetum plant, sassafras, buchu, uva ursi and strawberry leaves, cornsilk, marshmallow root and mallow flowers. Then there was "Compound Herb Tea Formula No 9099," which was reported to contain juniper berries, strawberry and sage leaves, gentian root, wild yam root, caraway seeds and stone root. Other Johnson nostrums, whose compositions were not given, were "Compound Herb Tea No 1" and "Dr. Lyncha A Johnson F and J Compound Herb Tea." A physician connected with the Food and Drug Administration testified that neither of these mixtures would be an effective treatment for any of the diseases for which they were sold. Accordingly, a fraud order was issued against Johnson March 12, 1943. It is also worth noting that in November 1940 in a federal court in Tennessee, Lyncha A Johnson pleaded guilty to violating the Food, Drug and Cosmetic Act in selling 5 of his nostrums under false and misleading representations for which he was fined \$1,500 and sentenced to be confined for 6 months in a jail or federal prison camp. These products were "Double Quick Liver Tablets," "Compound Herb Tea," "Blessed Herb Tea," "Herb Wash" and "St. Bernard Compound Herb Tea." Also this is presumably the person who once operated around Lake Village, Ark., under the names "Dr. L. A. J. Johnson," "Dr. George B. Williams" and "The Associated Doctors" and was twice prosecuted and fined in the courts in that vicinity for practicing medicine without a license. Around that time (1918) the Post Office Department issued its first fraud order against him for conducting a medical swindle through the mails, as reported in THE JOURNAL, August 17, 1918, page 590.

Unger-Vanderslice Vitaelixir—One Frank J Unger conducted a mail order scheme from Cleveland under the names Frank J Unger, Et Al, Chemists, "Unger Vanderslice, Chemists" and Unger Vanderslice Company, selling treatments known as "Vitaelixir Formulas" or "Course of Herb Formulas." He represented that this course when followed as directed, would, among other things, remove the cause of and cure arthritis, sciatica, rheumatism, lumbago, neuritis, neuralgia, heart trouble, high blood pressure and chronic gastric and intestinal disorders regardless of the age of the afflicted person or the duration or hopelessness of his condition, and that by its use diabetic persons using insulin could slowly wean themselves away from the insulin. Unger's literature described his "Normal Vitaelixir Course" as a series of "herb, root and mineral formulas," to be taken for a little over six months. The treatment consisted of "5 bottles of Alpha formula, 5 bottles of Tau formula and 2 bottles of Omega formula," the whole treatment selling for \$39, plus tax and mailing charges. Since Unger's various representations were obviously false, the Post Office Department summoned him to a hearing in Washington on a charge of fraud by mail. Two expert witnesses for the government testified that the Alpha formula contained emodin-bearing material, such as senna, cascara, jalap, podophyllin and ipecac, besides

sulfur, epsom salt, iron, phosphorus pentoxide, calcium, and traces of organic iodine, carbonate, sodium and kelp, plus some wintergreen and sassafras, that the sludge in the bottom of the bottle consisted of sulfate, magnesium, sulfur, sassafras bark, alfalfa, senna, jalap and cascara, and that the Tau and Omega formulas contained the same ingredients as the Alpha formula, though in slightly different amounts. An expert medical witness testified for the government that the action of these preparations ranged from laxative to purgative, that the proper treatment of arthritis would depend on the particular type of the disease and the cause thereof, the physical condition of the victim, and the possible existence of complications, that Unger's nostrums would not enable persons crippled with arthritis or rheumatism to regain complete use of their limbs and get completely well, as claimed by Unger, or have any beneficial effect whatever on the course of progress of an arthritic patient's disease or symptoms, and further, that the treatments and accompanying diet "would be adverse in all severe cases of diabetes." Unger testified that when suffering from arthritis himself and taking treatment in a hospital, he had concluded that "medical science knew nothing about arthritis," and, after leaving the institution, he had applied his "knowledge of chemistry to blood and food and experimented upon himself with various foods and diets," from which he determined "that the primary foundation of my sickness was food." However, since the medical testimony in the case showed distinctly that there was no scientific basis for Unger's claims to having a cure for the various conditions named, a fraud order was issued on April 23, 1943, debarring him from further use of the mails under the various names and titles that he had used.

STIPULATIONS

Agreements Between Federal Trade Commission and Promoters of Various Products

Following are abstracts of stipulations in which promoters of "patent medicines," medical devices and cosmetics have agreed, following action by the Federal Trade Commission, to discontinue certain misrepresentations in their advertising. These stipulations differ from the "Cease and Desist Orders" of the Commission in that such orders definitely direct the discontinuance of misrepresentations. The abstracts that follow are presented primarily to illustrate the effects of the provisions of the Wheeler-Lea Amendment to the Federal Trade Commission Act on the promotion of such products:

Hairtone Preparations—These include "Quinine Hairtone," "Quinine Hair Marvel," "Hairtone Scalp Formula" and "Hairtone Hair Straightener" and are put out by Matilda Richman, trading as the Hairtone Company and Hairtone Laboratories, Brooklyn, who in April 1943 stipulated with the Federal Trade Commission to discontinue the following advertising misrepresentations. That any of her products will promote the growth of hair or be an effective treatment for falling hair, that they would constitute an effective treatment or competent remedy for dandruff or are indicated for itching or sore scalp, or will result in a healthy condition of the scalp, or that they are new discoveries or vegetable compounds or herbal formulas. Further, she agreed to cease using the word "Hairtone" as a designation for her products, or representing that they impart tone to the hair or are powerful stimulants, she also was to desist from using the word "Straightener" in the name of any of her preparations, or from representing that they will straighten the hair, or using the word "Laboratories" in her trade name or in any manner which may tend to represent that she operates a laboratory. In May 1942 the Post Office Department issued a fraud order against the names Hairtone Company and Marvel Company and their officers and agents, debarring them from the use of the mails.

Krank's Hair Oil—In April 1943 the Consolidated Royal Chemical Corporation, Chicago, and Benson & Dall, Inc., which handles its advertising, stipulated with the Federal Trade Commission that they would discontinue the following misrepresentations in the advertising of this product. That it is a cure or remedy for dandruff or valuable in the treatment of this condition in excess of the removal of dandruff scales, that it will stop falling hair or early baldness, promote the development of a good head of hair, or offer any benefit in treating irritation of the scalp in excess of affording relief from minor irritation due to the presence of dandruff scales.

Me Ba—That this product will relieve or cure gas pains, indigestion, heartburn or ulcers, or reach the cause of stomach disorders, were misrepresentations which the Buenger Pharmaceutical Company of Denver agreed to discontinue in its advertising, in a stipulation that it entered into with the Federal Trade Commission in April 1943. In this the concern further agreed to reveal that Me Ba should not be used when abdominal pains or other symptoms of appendicitis are present, provided however, that such advertisement need only contain the statement, "Caution: Use only as directed" if the directions in the labeling should contain a warning to the same effect.

Thomas Lecithin Capsules with Vitamin D—Thomas C. James J and Rosie Martindale, doing business as Thomas Martindale and Company, Philadelphia, entered into a stipulation with the Federal Trade Commission in April 1943, agreeing to cease representing that this product is of value in treating nervous exhaustion, nervous headache, nervous irritability, or the various symptoms of nervousness such as irritability or loss of temper, that it will increase "nerve energy" or is a "brain food" or that when used as directed it will furnish the average minimum daily requirement of phosphorus.

Correspondence

SICKNESS, NOT HEALTH, INSURANCE

To the Editor:—The caption *Sickness, Not Health, Insurance* drew my attention to Dr. Haven Emerson's communication in *THE JOURNAL*, Nov. 27, 1943. Dr. Emerson believes that "it will add strength to our position and argument if we stick to the honest and correct term sickness insurance . . . , meaning insurance to meet the cost of sickness (institutional or medical)," avoiding wherever possible in the field of social insurance the term health insurance, which he associates with questionable political practices abroad and with the promotion of false hopes by "salesmen of New Dealism" and the "loose talk of health insurers" at home. He says further "In preparing to beat the Wagner-Murray-Dingell bill and similar legislation, we must tell the people that it compels them into sickness insurance and is in no honest respect a measure which will contribute to health promotion or protection."

Now one may note Dr. Emerson's dislike of the term health insurance without sharing it. One may agree with his definition of sickness insurance as it relates to the costs of illness without wishing to see the well established and more inclusive term displaced by the less. But when one reads the uncompromising clause I have put in italics, one may well call serious attention to a clearly drawn section of the Wagner bill which Dr. Emerson emphatically neglects.

This section is entitled "Grants-in-Aid for Medical Education, Research and Prevention of Disease and Disability." It directs and authorizes the Surgeon General of the Public Health Service "to administer grants-in-aid to non-profit institutions and agencies engaging in research or in undergraduate or post-graduate professional education. Such grants-in-aid shall be made with respect to each project (1) for which application has been received . . . and (2) for which the Surgeon General finds, with the advice of the council established under section 904, that the project shows promise of making valuable contributions to the education or training of persons useful to or needed in the furnishing of medical, hospital, disability, rehabilitation and related benefits provided under this act or to human knowledge with respect to the cause, prevention, mitigation or methods of diagnosis and treatment of disease and disability."

While it is clear that the term sickness insurance as defined by Dr. Emerson is not applicable to this part of the bill, it is equally clear that the term health insurance as used in the bill itself is in entire harmony with it. This would seem to be justification for its use by the Council on Medical Service and Public Relations, to which Dr. Emerson now takes exception.

In any case it is health we all desire, physicians and laymen. To us all it is the fundamental problem, however earnestly we try to spread the burdensome costs of sickness that, unprevented, strikes. And although we commonly think of prevention as the business of public health services, local and national, we all know that a hospital day saved is one day of health earned; that incipient illnesses are commonly aborted when seen under clinical conditions; that there is such a thing as clinical prevention. Private insurance companies find it profitable to capitalize this familiar fact.

Whatever the ultimate disposition of the Wagner-Murray-Dingell bill now before the Congress, its sponsors invite our serious consideration of it as an earnest attempt to contribute constructively toward the solution of our health problem not only by providing for the costs of medical emergencies as they occur but by reducing their incidence as well. In telling the people about it, would it not be well to minimize such misunderstandings as have already emerged by permitting the bill to speak, literally, for itself?

HARRY BEAL TORREY, M.D., Berkeley, Calif.

[The letter of Dr. Torrey was referred to Dr. Emerson, who replies:]

To the Editor:—The fact that the Murray-Wagner-Dingell bill, as now presented, includes financial subsidies to institutions of learning which offer professional and vocational training in the medical and accessory occupations hardly justifies its description as an instrument of public or personal health. Neither education in the medical sciences and arts nor research in the numerous contributing sciences has lagged in the United States of America, even without the suggested grants-in-aid from the federal treasury.

In fact, it may be soundly argued that a beginning of deterioration in higher medical education and in the productiveness of medical research will occur when the administration of federal funds through such a medical dictatorship as is proposed in the bill becomes a dominant factor of their support.

The bill does not offer insurance of the people's health, even if health were insurable.

The bill is a hodgepodge, perhaps intentionally so put together, to offer some kind of service or benefit to a wide variety of people who long to get something for nothing out of fabulous Uncle Sam.

There is included compulsory sickness insurance. Provision is made for supplementary institutions for diagnosis and treatment of disease. Universities and colleges are to be helped. Research is to be aided.

And yet there is not any evidence that the measures proposed will add materially to the progress or maintenance of medicine for the sick or for protection and promotion of public health, beyond what we have grown to trust and have observed with general and proper satisfaction for the past half century, without the new, burdensome, costly and necessarily arbitrary provisions of this bill.

It is of such stuff, of such confusion of thought, with lack of evidence, proof or logical reasoning that what the social promoters call "health insurance" is compounded. Health is a popular cloak to hide a profusion of injudicious and ill conceived ideas to the effect that by more medicine, free or for a pittance, health will be achieved. Nothing is less likely.

Dr. Torrey may well promote plans for voluntary sickness insurance and encourage the support of research within the great National Institute of Health, but when he urges compulsory insurance as a means of bettering national health he is just chasing a rainbow.

HAVEN EMERSON, M.D., New York.

VOLUNTARY NONPROFIT PREPAYMENT FOR HEALTH CARE

To the Editor:—The Special Article "Voluntary Nonprofit Prepayment For Health Care" in *THE JOURNAL*, February 26, rates comment only in regard to "what it didn't say."

This is to be expected in all material produced by those who persist in subordinating medical problems by placing them in the genus of economic or social questions. It is the habit of those who lack medical training and experience to confuse medical service (being seen), with medical care (proper treatment).

The defect and danger in the publication of this article is the fact that it masquerades as a good, when contrasted with proposed federal imposed medical care.

What should be emphasized, and deliberately is not, in this article is the fact that the word "voluntary" contributes no virtue toward medical care: experience everywhere proves that all systems tend to become compulsory.

All prepayment systems are insurance systems, and any insurance, medical or otherwise, which collects in cash and

pays its benefits in services is essentially bad. It adulterates the quality of the product desired by the purchaser and sold as genuine.

This is not theory; this is fact, learned by all insurance men in all kinds of insurance.

There is no substitute for "Collect in Cash—Pay in Cash." This is the rule required to protect the plane of medical practice as it is today and is supported by the entire profession.

Take hospital insurance for example, where still it is tolerated, through indirect compulsions. It is a success financially and as a social project, but the actual care of the concrete sick patient has dropped to that of a generation ago. Untrained, unknown, curious novices in the glamor of being in a profession have access to and are in contact with some dangerously sick people who are not indigent but are able to pay and do think they have paid for skilled care.

This is my daily experience in hospital work and can be corroborated by the honest testimony of every house or staff doctor or even the good nurse of twenty years ago. I wonder whether it is a medical success.

FRANK J. DORAN, M.D., Cleveland.

"YAWS, LEISHMANIASIS AND PINTA"

To the Editor:—In reply to the comments of Dr. H. D. Chambers (*THE JOURNAL*, March 4, p. 667) on my article on "Yaws, Cutaneous Leishmaniasis and Pinta" (*ibid.*, Oct. 23, 1943), I would say:

1. My statement that the macular eruption corresponding to that of syphilis is nearly always absent in yaws was based on my own observations as well as on the writings of many men with long experience in the study of yaws. In my article on "Syphilis and Yaws: Different Diseases" (Publication No. 6, American Association for the Advancement of Science) I stated that "most authors who record their experience with yaws either fail to mention the presence of a macular rash or state definitely that it does not occur in this disease." Schüffner in 1907 stated that he had seen this rash in 4 per cent of his cases, which is the equivalent of being nearly always absent.

2. In discussing the treatment of yaws, I said that "In the early stages the disease may be permanently cured by three successive injections of neoarsphenamine." A similar statement is made by no less an authority than Col. Richard P. Strong (Stitt, E. R.: *The Diagnosis, Prevention and Treatment of Tropical Diseases*, Philadelphia, Blakiston Company, 1942, p. 423). Speaking of neoarsphenamine, Strong said "Frequently one dose has effected a cure when given early in the disease, but in order to prevent relapses two or three doses are advisable." He further said "In the Philippines, using 0.10 gram of neoarsphenamine per kilo weight of patient with two treatments as the rule, but occasionally including a third one, clinical cures resulted in 94.3 per cent of cases." Strong also quoted the results of Morse, who treated 1,064 cases in Santa Domingo with arsphenamine. He revisited the country five years later and found that "after treatment with three injections a cure was likely to be permanent."

3. The fact that Dr. Chambers found no further loss of cartilaginous tissue following treatment of several active lesions of gangosa cannot be considered as a cure of that disease, whose synonym is mutilating rhinopharyngitis "and whose course, even when untreated, is marked by periods of comparative quiescence" (Sutton, R. L., and Sutton, R. L., Jr.: *Diseases of the Skin*, ed. 10, St. Louis, C. V. Mosby, p. 1277).

4. My statement that "there is eventually complete cross immunity between syphilis and yaws . . ." is not incompatible with the acquisition of syphilis by some patients previously infected with yaws. Such cases are, however, sufficiently rare

to call for publication whenever found (case of H. M. Hanschell, quoted by Dr. Chambers). The eventual development of complete cross immunity is well illustrated by the situation in the island of Guam, where no syphilis exists among the natives, practically all of whom have acquired yaws in childhood.

HOWARD FOX, M.D., New York.

BIOPSY OF THYROID IN THIO-CYANATE GOITER

To the Editor:—On page 568 of the February 26 issue of *THE JOURNAL* Dr. E. B. Potter of Seattle makes a statement about a previous publication of mine (*New England J. Med.* 227:594-602 [Oct. 15] 1942) to which I object on the ground that it is incorrect.

The statement in question relates to a biopsy of the thyroid in a case of thiocyanate goiter, and on it Dr. Potter makes the comment that "the microscopic report is inconclusive in this case." My statement actually was as follows (p. 597): "The biopsy showed a wildly hyperplastic thyroid." What there is "inconclusive" about this statement I am quite unable to perceive. If Dr. Potter had called it "incomplete" I would have made no protest, but to call it "inconclusive" strikes me as preposterous. Perhaps my use of the word "wildly" was revolting to a pathologist, but I cannot understand how there could have been any doubt about its meaning in the connection in which it was used.

As a matter of fact the statement that Dr. Potter cites was a preliminary one. In the *Annals of Internal Medicine* (19:829 [Dec.] 1943) Rawson, Hertz and Means publish a full account of this case and others with photomicrographs.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: *Oral and Written, Part I*. Chicago, New Orleans, New York and San Francisco, October. Final date for filing application is August 1. Sec., Dr. G. A. Caldwell, 3503 Prytania St., New Orleans.

AMERICAN BOARD OF OTOLARYNGOLOGY: *Oral*. New York City, June 1-4. Sec., Dr. Dean M. Lierle, University Hospitals, Iowa City, Ia.

AMERICAN BOARD OF PATHOLOGY: *Oral and Written*. Chicago, June 7-8. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit.

AMERICAN BOARD OF PEDIATRICS: *Written*. Locally, Sept. 22. *Oral*. St. Louis, Nov. 8 or 9. Final date for filing application is July 8. Sec., Dr. C. A. Aldrich, 115½ First Ave. S.W., Rochester, Minn.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Venereal Diseases: Conviction of Infected Person Exposing Another by Sexual Intercourse to Venereal Disease.—An Oklahoma statute makes it a felony for any person after becoming infected with venereal disease and before being discharged and pronounced cured by a physician to marry or expose any other person to such disease by sexual intercourse. An information was filed against the petitioner charging that on a stated day she, being infected with a venereal disease, committed the crime of exposing a stated person to a venereal disease by having sexual intercourse with him. She plead guilty and was sentenced to the state penitentiary. Later a habeas corpus proceeding was instituted in the criminal court of appeals of Oklahoma, alleging that the information in question was fatally defective and was insufficient to confer jurisdiction on the trial court because it failed to negative the fact that she had been "discharged and pronounced cured by a reputable physician in writing," which, so it was alleged, the statute specifically makes an element of the offense.

In *Epps v. State*, 69 OKL. Cr. 460, 104 P. (2d) 262, said the criminal court of appeals of Oklahoma, this court sustained an information under the identical statute on which this information is based. The information in that case was similar in language to the information here in dispute. It was alleged in the information involved in the *Epps* case:

That the said M. T. Epps did then and there knowingly, wrongfully and unlawfully and feloniously, by the act of copulation, communicate to the said Ruth Epps, a venereal disease, to wit: syphilis, contrary to the form of the statutes in such cases made and provided and against the peace and dignity of the State.

Although the specific question now raised as to the necessity of the information's of negating the fact that the accused had not been cured was not considered in disposing of the *Epps* case, we did hold in affirming that judgment that there were no fundamental defects in the information or the proceedings before the trial court which would deprive the court of jurisdiction to sentence the accused. There are many decisions of this court wherein we have held that exceptions in a statute similar to the exception herein, which provides for a written release from a reputable physician, are a defense to be pleaded by the defendant. It is fundamental that it is not necessary in an information to allege any fact which it is not necessary for the state to prove to secure a conviction. Under the statute here involved, if we should hold that the state had the burden of proving that the accused had not been discharged and pronounced cured by a reputable physician in writing, it would create an almost insurmountable burden on the state. The state would not be in possession of the intelligence as to who had been administering treatment to the accused or whether she had even been given treatment for her venereal disease. The prosecution surely would not be required to bring all of the physicians in the community to court to inquire whether they had discharged the patient as cured. To this court it is apparent that this provision was inserted in the statute by the legislature as a matter of defense which may be interposed by an accused, and when such defense is made it then should be submitted to a jury for their determination as to whether the accused had been discharged as cured by a reputable physician in writing and had innocently exposed another person to a venereal disease under the honest belief that she was no longer infected. The state has the burden of proving beyond a reasonable doubt that the accused had become infected with a venereal disease and that subsequently thereto she had exposed another person to such disease by some of the means set forth in the statute.

The court accordingly held that the information filed against the petitioner in the trial court was sufficient to allege a violation of the act and that the commitment of the petitioner of a plea of guilty to that information was sufficient authority for her confinement in the penitentiary. A writ for habeas corpus was accordingly denied.—*Ex parte Brown*, 139 P. (2d) 196 (Okl., 1913).

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1934 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- Abdominal Pregnancy Requiring Secondary Removal of Placenta. J. W. Pearson Jr and J. Parks—p 127.

Harmful Influence of Pregnancy on Advanced Tuberculosis.—Cutler reviews the immediate and late effects of pregnancy on advanced tuberculosis in 26 white women who were treated with collapse therapy to control the tuberculosis before giving birth to one or more children. These women have been under constant clinical and roentgenologic observation for various periods of time during the past fifteen years. The average for the group was nine years. These 26 women had forty-eight pregnancies following collapse therapy and gave birth to 40 children, of whom 36 are alive and well. Pregnancy can and does affect some patients with tuberculosis unfavorably. Exacerbation may occur either in the early months of pregnancy or within the first few months following delivery. Collapse therapy has minimized this risk. If the diseased area is well collapsed, the sputum free of bacilli and the collapse maintained throughout pregnancy there is little or no risk of reactivating the process. Such women may safely undertake one or more pregnancies. If there is disease in both lungs and only the "worse" lung is treated with localized collapse therapy, the disease in the uncollapsed lung, although quiescent before pregnancy, may become active in approximately 30 per cent of the cases. In about half of this number collapse therapy may actually be essential to control the reactivated disease in the untreated lung. The possibility of reactivating quiescent tuberculosis in an uncollapsed lung is not in itself a contraindication to pregnancy. Permission may be given as long as the patient is kept under observation and is willing to accept collapse therapy when it becomes necessary. Pneumothorax therapy may be considered as an alternative to therapeutic abortion in the presence of active tuberculosis first recognized during the early months of pregnancy. Only collapse therapy which produces adequate localized collapse of the diseased portion of the lung, such as pneumothorax, maintenance oleothorax or thoracoplasty, will prevent reactivation of the disease. Indirect collapse, such as phrenic nerve interruption, is not enough. Inadequate collapse therapy may be considered the same as no collapse therapy as far as the effect of pregnancy on tuberculosis is concerned. The majority of such patients with advanced disease do poorly, and pregnancy is inadvisable.

Constitutional Type of Female Precocious Puberty.—Novak reports 9 instances of precocious puberty in girls aged 15 months, 2 years, 2 years 8 months, 4 years, 4½ years, 6½ years, 7 years, 7 years and 7½ years. As to why an otherwise normal puberal mechanism is awakened at an abnormally early age no explanation seems plausible except on a chromosomal or genic basis, so that the designation of "constitutional" seems appropriate for this group. Cases of this type are far more common than those due to granulosa cell tumors, which gynecologists especially are apt to think of first in association with precocious puberty, often resorting to exploratory laparotomy in such cases. Biopsies in several instances has convinced the author that, unlike girls with granulosa cell tumor, those of constitutional type may not only menstruate but also ovulate at abnormally early ages. This would explain the occurrence of pregnancy at extremely early ages, as in the remarkable case reported from Lima, Peru, in 1940 of a full term pregnancy in a child 5 years and 8 months old. The most important practical points in the management of these cases are the physiologic management to avoid the development in the child's mind of self consciousness or a sense of inferiority or abnormality and protection against the possibility of insemination.

Meningococcal Infections.—Smith and his collaborators review 51 meningococcal infections among patients admitted to the Boston City Hospital in the two year period beginning Sept. 1, 1940. Included among these were 43 with meningitis and 8 with meningococemia without clinical evidence of meningitis. There were 9 deaths among the former and none among the latter. Any one or more of the characteristic findings of meningococcal meningitis may be absent in any given patient. A tentative diagnosis of meningococcal meningitis can be made in almost every instance by examination of a gram stained smear of the cerebrospinal fluid or its sediment. Group II meningococcus should be carefully distinguished from the gonococcus, especially when the organism is recovered only from the blood. All except 2 of the patients with meningitis who recovered showed objective signs of clinical improvement twenty-four hours or less after chemotherapy. The initial dose of a sulfonamide should be administered intravenously even if patients appear only moderately ill when first seen. Patients with a

relative bradycardia, even though they appear only moderately ill on admission, should be observed closely for evidence of increased intracranial pressure. Lumbar puncture still has a place in the therapy of meningococcic meningitis for diagnosis and for the relief of symptoms of increased intracranial pressure. Normal cerebrospinal fluid sugar values obtained after the use of sulfonamides or of parenteral dextrose therapy are of no value by themselves in estimating the progress of the disease. Pulmonary involvement is quite frequent in the course of meningococcic meningitis. It probably represents a local infection by the meningococcus either alone or with other organisms. Pneumonia due to the meningococcus may occur in the absence of meningitis, but such cases were not recognized in the present series.

Clinical Aspects of Meningococcic Infection.—Adams states that as the result of experience gained in army hospitals his conception of meningococcic infection has been appreciably altered. Meningococcic disease should be regarded as a blood stream infection of which cerebrospinal meningitis is but one manifestation. Cases without meningitis are common. When the disease exists in a community every person with upper respiratory symptoms should be regarded with suspicion and closely watched. The usual forms in which meningococcic disease may appear are: (a) Meningococcemia with acute meningitis. Diagnosis can and should be made before the appearance of signs of meningitis. Especially in the presence of upper respiratory symptoms, severe headache, apathy, restlessness or delirium, muscle aches, slight stiffness of the neck or an eruption which is not characteristic of the common exanthemas are indications for diagnostic lumbar puncture. (b) Acute fulminating septicemia with or without meningitis, manifested by sudden onset with prostration, rapidly developing profuse macular and petechial eruption, early and rapid circulatory collapse followed by death, often within a matter of hours. (c) A less severe form of bacteremia characterized by inflammation of one or more joints, a less intense eruption, often macular rather than petechial, and aching in the muscles of the extremities. (d) A chronic form of bacteremia in which bouts of fever accompanied by joint pains and mild eruption occur at intervals of weeks or months with intervening periods of relatively good health. In any of these last three groups the clinical picture of meningitis may develop, but the diagnosis can and must be made in the absence of symptoms of meningeal involvement. Early treatment with a sulfonamide drug is almost certain to effect a cure except in cases of acute fulminating septicemia and in meningitic cases in which treatment is started late. The first dose should be given intravenously. Fluid intake must be high. Antimeningococcus antitoxin should be tried on all severely ill patients. Adrenal cortex extract may counteract the circulatory collapse associated with the fulminating septicemia.

Epidemic of Dengue Fever.—Kisner and Lisansky state that approximately 1,200 cases of dengue fever occurred in army personnel in and around a coastal town on an island in the South Pacific from March 1, 1943 to April 30, 1943. Six hundred and twenty-two were hospitalized and 318 cases of this group were analyzed as to symptoms, physical aspects and laboratory data. The island harbored numerous endemic cases of dengue fever among the civilian population, a large number of newly arrived nonimmune army personnel and the most efficient mosquito vector, *Aedes aegypti*. Cases which occurred early in the epidemic were more atypical than the subsequent ones and caused some difficulty in diagnosis. The onset was sudden in about 93 per cent after an incubation period of six to ten days. Aches and pains in one or more sites occurred in 99 per cent. The frontal headache, backache and generalized aches and pains were common complaints. Feverishness and chilliness were frequent and early symptoms. Weakness, abdominal pain and insomnia occurred next in order of frequency. Dizziness, nausea, burning of the eyes, photophobia and distortion of taste were complained of in a small number of cases. Diarrhea, itching of the skin, sore throat, vomiting, constipation, numbness and tingling of the extremities and epistaxis were last in order of frequency. The temperature curve was saddle-back in about 66 per cent of cases. A relative bradycardia was found after the second day of illness in

97 per cent. A rash was present in 37 per cent of all cases. A diffuse flushing of the skin, primarily of the face and chest, was seen in about one fourth. About the same number showed reddening of the conjunctiva. Adenopathy, pharyngeal vascular congestion, hyperesthesia or cyanosis of the fingers and toes were found in a small number. Laboratory examination revealed leukopenia and a Schilling shift to the left. Abnormal lymphocytes with a vacuolated cytoplasm and coarse granular inclusions was a rather constant finding. The convalescence was moderately prolonged. All cases responded to symptomatic therapy and there were no complications.

Mortality in Hypertension.—Flaxman compared the mortality statistics of 350 hypertensive patients treated surgically by Peet and his co-workers with the mortality of 244 hypertensive patients observed by himself and treated only medically. He found little difference between the two groups. He concludes that it is doubtful whether so-called specific surgery alters the course and prognosis in cases of hypertension, including those with malignant hypertension.

Penicillin and Sulfadiazine in Intraocular Infections.—Von Sallmann injected various strains of *Staphylococcus aureus* into the anterior chamber of the eyes of chinchilla rabbits with simultaneous injury of the lens to produce a reliable standard lesion for chemotherapeutic experiments. Combined oral and topical use of sulfadiazine was beneficial in 21.7 per cent of the eyes with purulent endophthalmitis thus produced when the treatment was initiated six to seven hours after inoculation. Penicillin applied topically with the first treatment six to seven hours after inoculation controlled the infection definitely in 62.5 per cent and possibly in 75 per cent of the eyes. Intralenticular injections with *Clostridium welchii* caused destructive endophthalmitis. Neither sulfadiazine nor penicillin therapy begun six hours after the intralenticular injection of *Cl. welchii* had any effect on the resulting endophthalmitis.

Symptomatology of Duodenal Diverticula.—Warren and Emery studied 103 cases of diverticulum of the duodenum found in the records of the Peter Bent Brigham Hospital from 1914 to 1941. The study did not reveal any typical symptomatology. The diverticula found in the first portion of the duodenum are usually of the false type and appear to be associated in most instances with duodenal ulceration. Those in the second portion are usually a true herniation of the mucosa through the muscular wall. A fair number of these show inclusions of pancreatic tissue. Four of the cases showed evidence of inflammation within the sac, and 1 a localized abscess. The finding of a diverticulum in the first portion of the duodenum usually means the presence of peptic ulceration. One is justified in treating such persons as if they had a duodenal ulcer. A sac which fails to empty satisfactorily will give symptoms. A sac which does not retain the barium is less likely to be a source of trouble than one which shows a retention. Smaller pockets are less likely to be of clinical importance than the larger ones.

Lymphosarcomas of Intestine.—According to Winkelstein and Levy, lymphosarcoma of the intestine is a rare disease of unknown causation. The small intestine is more often involved than the large intestine. Multiple intestinal lesions are not uncommon. Lymphosarcoma may occur at any age. The authors present a summary of 15 cases observed at the Mount Sinai Hospital from 1932 to 1942. Eleven of the patients were men. There were no children. Nine patients were between the ages of 29 and 41 and 6 patients were between 52 and 65. The lesion of 9 patients was resected, of whom 4 died immediately after the operation. All the patients who survived the operation were subjected to radiotherapy. Two of the 3 other patients being given surgical treatment underwent exploration only, and in the third the lesion was merely sidetracked. This patient survived four years. Of the 2 undergoing exploration 1 died immediately and the other was lost sight of. Of the 3 patients not surgically treated 1 survived eighteen months with radiotherapy; 1 lived for four and one-half years without treatment and then survived another eighteen months with radiotherapy; the third patient died without treatment in three months. The histologic differentiation into small cell lymphosarcoma and reticulum cell sarcoma is unimportant clinically. Abdominal pain, loss of weight, pallor and abdominal mass or masses are the chief symptoms. There is frequently a characteristic sigmoidoscopic picture which resembles the convoluted surface of the brain. Sooner or later intestinal lymphosarcoma becomes a systemic disease. It is invariably fatal. With surgical removal plus radiotherapy the duration of life is usually less than one year. Occasionally patients live several years.

Pulmonary and Intestinal Changes in Strongyloidiasis.—Berk and his associates call attention to the fact that, although strongyloidiasis is primarily a disease of the warm climates and ordinarily rarely encountered in the temperate zones, the migration of persons from the southern part of the United States to the industrial war centers of the North and East and the return home of men who have completed military service in tropical climates will probably bring about a wide dispersal of the disease. The authors describe the life cycle of *Strongyloides stercoralis* and the pathologic physiology and clinical aspects of strongyloidiasis. They encountered 2 cases of strongyloidiasis in the past year in both of which pulmonary symptoms had appeared prior to their coming under observation. They emphasize that sputum and stools should be examined for evidence of *Strongyloides stercoralis* in any case with respiratory symptoms of obscure etiology, especially if there is an eosinophilia and x-ray evidence of transient pulmonary infiltrations. Pulmonary changes due to intestinal parasites should be suspected whenever dyspnea, cough or hemoptysis occurs in an individual who also complains of abdominal pain, diarrhea or other digestive tract difficulties. Granulomatous tumor-like masses may develop in those sections of the intestine heavily parasitized by *Strongyloides stercoralis*. Enteritis is a feature of strongyloidiasis, and abnormalities in the x-ray appearance of the small intestine may be found in patients with this disease.

Vitamin K in Hemorrhagic Disease of the Newborn.—Pray reports the prophylactic effect on hemorrhagic diathesis in the newborn of antepartum administration of menadione to mothers. Some observations on treatment have also been made. The expectant mothers were divided into three categories. One group received menadione before delivery for periods varying from three days to six weeks; a second group was treated during labor; a third was given no medicinal vitamin K. A preparation of menadione in tablet form was used. The author utilized a simple test requiring only 0.1 cc. or less of capillary blood in making multiple determinations of prothrombin values in newborn infants. The results obtained confirm the observations of other investigators that the administration of vitamin K to expectant mothers, either during the latter part of pregnancy

or during labor, results in approximately normal prothrombin values in their infants and virtually eliminates the prolongation in prothrombin time, which usually occurs in untreated cases between the second and fourth days of life. Menadione is one of the most potent preparations having vitamin K activity. The incidence of retinal hemorrhages in the newborn was greatly reduced in infants of mothers treated with menadione during labor or prior to labor. The results suggest that the reduction is greatest in the cases in which treatment is instituted before the onset of labor. These findings are of particular interest in their possible relationship to intracranial hemorrhage. The introduction of formula feedings during the first few days of life counteracted hypoprothrombinemia. Three infants with hemorrhagic disease of the newborn were rapidly cured by administration of vitamin K. In 2 cases this was administered intramuscularly, and in 1 case by mouth. It is considered advisable to administer vitamin K to all mothers either during early labor or daily during the last few weeks of pregnancy. In case this is not possible, vitamin K should be given to the infant during the first twelve hours of life either by mouth or parenterally. If none of these courses are feasible, supplemental formula feedings given the baby during the first two or three days will raise the prothrombin level effectively. Treatment of hemorrhagic disease itself should consist in prompt administration of vitamin K, preferably by a parenteral route.

Canicola Fever (Leptospirosis Canicola).—According to Tievsky and Schaefer, infection of man with *Leptospira canicola* is a rarely reported occurrence. The condition occurs much more frequently than has been recognized. A Negro aged 23 was hospitalized with high fever. One week before admission he cut his foot with glass. The various tests and examinations made included agglutination tests with *Leptospira icterohemorrhagiae* and *L. canicola*. The titer was 100 times as high with *L. canicola* as with *L. icterohemorrhagiae*. The authors point out that canicola fever is transmitted through the urine of infected dogs. It has been shown that leptospiruria in dogs differs from the comparable situation in rats in that the latter

continue to excrete leptospiras in the urine for the rest of their lives, while the former are shedders for only a limited period. The infection is perpetuated among dogs because of their habit of licking urine and intimate contact with genitalia. The disease in man results from the intimate contact with dogs in the stage of leptospiruria, the infection following the ingestion of contaminated material. There is probably a large canine reservoir in the United States with some potentiality for human infection. The authors stress the importance of doing agglutinations against both *L. icterohemorrhagiae* and *L. canicola* simultaneously because of the similar clinical picture resulting from infection with these organisms and the occurrence of a strong cross agglutination between them which may result in an erroneous diagnosis of Weil's disease.

Transient Nervous Hypertension and Essential Hypertension.—Rogers and Palmer direct attention to transient elevations in blood pressure that are observed in men during physical examinations for the armed forces. During one month at the Office of Naval Officer Procurement, Boston, 222 (14 per cent) of 1,574 applicants had mild variable hypertension at the initial examination. The systolic pressure varied from 140 to 160 mm. and occasionally higher, and the diastolic pressure ranged from 95 to 110 and rarely as high as 120. About one third of the subjects have only systolic hypertension. Organic changes as judged by the history, physical examination and urine examination were absent. Transient nervous hypertension is evidence of a nervous pressor reaction and is often accompanied by one or more adrenergic manifestations, such as tachycardia, sweating, erection of hairs and disturbed rhythm. Persons with transient nervous hypertension have a somewhat more noticeable rise of the blood pressure in response to cold than do normal controls, but definitely less than do patients with definite but mild early hypertension. The familial predisposition to degenerative vascular disease of those with transient nervous hypertension appears less than in patients with definite essential hypertension. The prognosis of nervous hypertension as indicated by a long follow-up study of 25 cases regarding both mortality and morbidity before middle age is excellent.

Pitfalls in Roentgen Diagnosis of Intracranial Disease.

—After warning against drawing conclusions from inadequate films, Schwartz mentions among other factors the high incidence of a calcified pineal body and the estimation of its displacement. Another pitfall is the misinterpretation of an anomalous configuration and distribution of circulatory channels, particularly the diploic venous channels. The sutures are occasionally confusing. Convolutional impressions are often misinterpreted as evidence of intracranial pressure when in reality they are quite innocuous. Another frequent source of error in intracranial diagnosis is the misinterpretation of a demineralized sella turcica as evidence of pressure atrophy when actually it may be due to a congenital lack of bone calcium, to an abnormality of calcium metabolism of systemic origin or to a normally thin bone. This again emphasizes the importance of always considering the general physical status of the patient when interpreting roentgenographic changes. Symmetry of the skull is never perfect, so that we must be wary in interpreting asymmetry as abnormal. This is particularly true of the petrosa. From 10 to 15 per cent of skulls show congenitally asymmetrical petrous pyramids, one being aerated in a comparatively normal manner while the other contains very few air cells. The mistake must not be made of drawing conclusions from a study of only one part of the skull. Every structure must be carefully studied and evaluated with reference to the whole.

Fibrin Fixation of Skin Transplants.—Tidrick and Warner employed fibrin fixation of skin transplants in 122 operations on 53 patients. There were three categories of wounds: (1) primary grafting procedures in which clean operative wounds have been grafted immediately, (2) burns and (3) other types of chronically infected granulating wounds. Fibrin fixation of tissue in operative procedures can be readily accomplished by the use of plasma and purified thrombin. Artificially supplied fibrin clots obtained in this manner proved to be of distinct mechanical aid in skin grafting operations. The results suggested that the fibrin also promotes healing, but additional data are needed for definite conclusions on this point. Thrombin in sterile and highly purified form is now available for clinical trial. The technic of fibrin fixation is simple and might be used to control the amount and site of deposition of fibrin in various types of operative procedures. Many possible applications suggest themselves. There have been no untoward results from the use of thrombin and plasma for fibrin fixation in the 122 operations in which the authors have used this technic.

Aortic Hypoplasia.—Werley and his associates define aortic hypoplasia as that condition in which the lumen of the arterial vessels in the greater circulation remains abnormally small and the walls abnormally thin and elastic. In a series of 4,500 necropsies performed by the Department of Pathology of the University of Texas Medical Branch, aortic hypoplasia was recorded twenty-five times. Only 4 of the 25 cases showed cardiac enlargement. An extreme degree of aortic narrowness is probably required to produce heart disease, and it usually occurs only when there has been an excessive strain on the heart. Early heart failure may follow puberty, at which time the body in general grows more rapidly than the aorta. Increased elasticity at first somewhat compensates for aortic narrowness, but diminishing elasticity with age, even between 20 and 30 years, may explain the onset of failure among older patients. The rapid onset probably results from the limited reservoir of the small aorta causing dilatation of the already hypertrophied left ventricle. This may lead to a relative mitral insufficiency so that right heart failure appears early, as is seen in all 3 cases reported in this paper. The most important diagnostic method is fluoroscopy. The posteroanterior and left

anterior oblique views reveal best any changes in aortic size. If the aorta is small enough to cause heart failure a narrow aortic shadow and a small aortic arch and knob will be seen. The upper arch will be smaller than the pulmonary artery. There was no evidence of persistent thymus gland in the 3 patients seen by the authors. All had, in common, youth, vigorous exercise, brief duration, poor response to treatment and fatal outcome; necropsy revealed a small aorta, an enlarged and dilated heart with myocardial degeneration and fibrosis. Early recognition and discontinuance of strenuous exertion would no doubt greatly prolong life.

Carcinoma of Prostate Gland.—Kahle and Beacham studied 342 cases of carcinoma of the prostate treated at Charity Hospital of Louisiana over a four year period. A detailed study as made of the 88 cases (25.1 per cent) with a fatal outcome. Early diagnosis of prostatic carcinoma is difficult chiefly because the onset is insidious and the early clinical picture is obscure. Patients are seldom seen until their disease is far advanced. The causes of death of patients with carcinoma of the prostate are various and include, as well as the disease itself, chiefly urinary tract infection and degenerative diseases common to men of advancing years. Because of the status of many patients with carcinoma of the prostate gland, therapy usually must be directed chiefly toward the postponement of death and toward keeping the patient comfortable during the remainder of his life. Radical perineal prostatectomy is possible in only a minimal number of cases and is attended with a high mortality. Transurethral resection of the gland is the most practical operation for general purposes. The recent development of castration and of diethylstilbestrol therapy in the treatment of carcinoma of the prostate has permitted results not heretofore achieved with any other form of therapy. Neither method is curative, but both bring about in a large number of cases at least temporary improvement in the general status, relief from pain, regression of metastases and local regression of the malignant growth. The authors prefer diethylstilbestrol therapy for all patients to castration and regard it as more rational.

Hyperthermia in Resistant Gonococcal and Nonspecific Urethritis.—King and his associates used hyperthermia with the Kettering apparatus in resistant gonococcal and nonspecific urethritis. They tabulate the results obtained in 418 cases with sessions of fever at 106 F. with and without premedication with various sulfonamides. They conclude that high fever mechanically produced is the treatment of choice for resistant gonococcal urethritis. It is much more effective when combined with sulfonamide premedication. The duration of fever required varied with the individual case, but sessions of six to eight hours produced a high proportion of successes. Cases in which hyperthermia was not followed by immediate cure frequently responded to measures which had previously failed. Hyperthermia was less effective but still of value in the treatment of resistant cases of nonspecific urethritis. The advantages of premedication with sulfonamides were less effective in these cases. The potential dangers of this treatment can be reduced to a minimum by careful and skilful technic.

Physiologic and Biochemical Changes Following Hypertherm Treatment.—Wallace and Bushby point out that treatment which involves the maintenance of the body temperature at 106 F. for a period of eight hours imposes a severe strain on the vital organs. They investigated physiologic and clinical changes in patients undergoing hyperthermia treatment for gonorrhea. Clinical studies were made on 254 cases in which hyperthermia treatment was being given at 106 F. for eight hours. Thirty-seven of these cases have been the subject of a detailed clinical, hematologic and biochemical investigation. The most constant and prominent features have been the development of anoxia and bilirubinemia, progressing to manifest clinical jaundice in 37 cases. Hippuric acid tests showed a considerable reduction in liver function. Continuous oxygen and carbon dioxide therapy lessened but did not abolish anoxia. Administration of oxygen and carbon dioxide appeared to prevent the development of circulatory collapse. Vomiting was less frequent after the introduction of oxygen therapy. This complication of circulatory collapse is a failure of the vasomotor and respiratory centers and is not due to a reduction in the circulating blood volume or to myocardial failure. Morphine is absolutely contraindicated. There is a transient polymorphonuclear leukocytosis and a transient hemodilution. There is a small transient rise in nonprotein nitrogen and a tendency for plasma chlorides and urinary chlorides to fall. Premedication with 6 Gm. of sulfathiazole does not increase the hazards of this treatment. Indications for prehypertherm and posthypertherm treatment are given.

Prisoner of War Mentality.—Newman states that the number of prisoners ultimately returning to Britain alone will be many hundreds of thousands and, that to countries throughout the world, millions. The return of these prisoners will entail a flooding of the country with men and some women who have experienced circumstances not necessarily harder but quite different from the majority of the others. The effects of internment are physical and mental. The treatment of the physical effects after release is probably a matter of good food, elementary medicine and pleasant conditions. In mental convalescence, common sense is the guiding principle. The use of individual psychologic treatment is debatable; it may carry with it a public acknowledgment of mental abnormality, which must at all costs be avoided. Barbed wire disease is a *misnomer*. It is wrongly called a disease and perhaps is better termed a mental attitude. This mental attitude is built up from four phases through which the average internee passes. Stage 1 is the breaking-in period, stage 2 the period of convalescence, stage 3 the lengthy period of boredom and stage 4 the repatriation period. The author lays emphasis on the importance of the typical mental reactions which follow release as opposed to those shown while in the camp. The great majority of returned prisoners of war do not give rise to concern, but those showing excessive mental reactions or an undue persistence of symptoms may need assistance.

Traumatic Arterial Spasm.—In his Hunterian lecture Cohen presents a survey of arterial spasm based on 120 collected and personal arterial incidents in most of which spasm was a feature and an experience with air raid casualties running into four figures. The peculiar responses depend on the natural contractile properties of the smooth muscle of the arterial wall. The sympathetic system is not concerned in the local spasm of the main artery, but by keeping the cutaneous circulation closed the sympathetic system prevents the blood pooling in the relatively unimportant skin areas and so starving the muscles. Thus where the sympathetic fibers are destroyed, as in associated nerve injuries, the onset of a Volkmann lesion may be favored. The muscle circulation cannot be assessed from observation of the skin circulation. The operation of arteriectomy has no reflex effect in cases of arterial spasm; it may be of value, but purely for mechanical reasons, such as removal of a clot or of a contused segment of the vessel in which a clot is likely to form. A local arterial bruise does not by itself act as an irritant focus and maintain spasm: this was initiated by the original blow. Pulling on the distal half of a vessel during ligation or embolectomy may initiate a spasm lasting varying times. Venous trauma is unlikely to cause reflex arterial spasm. Hemorrhage from a divided vessel is checked by the spasm induced by the stimulus of the elastic recoil of the vessel. When this recoil is prevented, contraction is effective. Tourniquet spasm and the allied condition following crushing injury are of an entirely different type. They are a shock response for which nerve block and icing of the limb till the circulation is restored are advocated. In the arterial spasm following fracture early operation is needed. Repeated manipulations during the first forty-eight hours are to be avoided. Segmentary spasm is regarded as innocuous, but exploration is advisable because the state of the vessel cannot otherwise be determined. In the management of the anemic limb, elevation is important. The limb should be kept cool, not iced. Icing is reserved for the crushing injury. Spasm of the deep vessel is not induced by refrigeration of the limb. Attention to the patient's general condition is the primary consideration.

Late Results of Perforated Peptic Ulcer.—Wakeley states that since the bombing of Britain began there has been an increased incidence of perforated peptic ulcer in both sexes. This has been noticeable among civilians and the personnel of the fighting forces. The author investigated the late results of operation in naval personnel. A follow-up of 103 patients with perforated peptic ulcer operated on at a Royal Naval hospital between 1924 and 1934 showed that 44 per cent are still serving in the Royal Navy. The operative mortality was only 8 per cent, partly because the average interval between perforation and operation was only four hours and partly because the patients were relatively fit men of an average age of only 32 years. Hence the contrast with a control series of civilians in which the average age was 46, the average interval between perforation and operation ten hours and the mortality 20 per cent. The patient with a perforated peptic ulcer need not be invalidated from the service, nor need a history of perforation necessarily mean refusal by recruitment medical boards.

Allergic Dermatitis from Footwear. A. Robins.—p. 345.
Intercalary Dislocation of Patella. S. V. Humphries.—p. 347.

Causalgia in War Wounds.—Copley shows that causalgia is an intractable form of neuralgia, neither truly somatic nor exactly following the distribution of peripheral nerves. It is characterized by a peculiar burning type of pain. An affected limb is cool but pink, extremely sensitive to touch and minor irritations. Vascular instability is present. The pain is periodic in intensity and variable in distribution but may be of such severity as to demand morphine for relief. The primary cause is always nerve trauma, but the trauma may be trivial, transient or indirect, and it is a curious observation that a nerve which has been shaken or bruised more commonly sets up causalgia than one which has been completely divided. The author describes several case reports to illustrate this. Causalgia is clearly not a neuritis or inflammation of the normal channels of communication between receptor organs and the areas of appreciation in the brain. There is sufficient evidence to show that causalgia is a disease of the vasomotor nerve supply to the limbs either of the efferent or of the afferent fibers or of both. Causalgia is a peculiar reflex set up by the pain of trauma and bound up with the blood vessels. If it is accepted that causalgia is a fixed sympathetic reflex, it must be broken somewhere in its path. To produce lasting results in causalgia of the arm the stellate ganglia must be exposed and, in the leg, the lumbar ganglia.

Diabetes Insipidus After Gunshot Injury of Head.—Lambrecht reports a gunshot injury of the head sustained by a soldier. The man felt extreme thirst. Roentgenoscopy revealed fractures of the coronoid process of the lower jaw bone on both sides. The sella turcica appeared normal, and there was no fracture at the cranial base. There was hardness of hearing and a positive Romberg sign. There was some involvement of the facial nerve on the right side. The rest of the cerebral nerves showed no impairment of function, and there were no motor or sensory disturbances of the trunk and the extremities. The patient drank 25 liters of water daily, but the administration of phenobarbital and of hypophysin gradually reduced

the fluid intake to 4 liters in the course of four weeks. The author assumes that the missile in passing through caused considerable contusion of the adjoining parts of the brain, particularly the hypophysis and the diencephalon.

Causalgia After War Injuries.—Wanke defines causalgia as a pain syndrome with vasomotor and trophic sympathetic disturbances. The pain is elicited by tactile, thermic, sensory or psychic stimuli of subthreshold intensity. The patients have a morbid desire to lessen the pain by keeping the involved extremity moist. Some moisten all uncovered parts of the body. This condition originates in local injuries of the median, ulnar or sciatic nerves. Even injuries of the soft parts in the regions innervated by these nerves may cause causalgia. In one case of causalgia with partial injury of the sciatic nerve microscopic examination disclosed an inflammatory process in the perivascular lymph channels and in the lymph spaces of the intraneural vessels. Microscopic studies of 10 neuromas of the sciatic, median or ulnar nerves disclosed no such changes. This explains not only the pathophysiologic disturbances of causalgia but also its long duration and its refractoriness to treatment, because the inflammation ascends intraneurally to the spinal cord. Cyanosis usually exists in the diseased limb. A spasm of the arterioles exists with subsequent stasis in the capillary system and in the venules. The resulting interference with the metabolism and the gas exchange induces absorption of toxic products, and this in turn maintains the lymphogenic perivascular inflammation of the intraneural vessels. This represents a vicious circle which can be interrupted only by intervention on the sympathetic. Resection of the sympathetic trunk of the cervicodorsal thoracic chain for the upper extremity and of the lumbosacral chain for the lower extremity is immediately effective as regards the pain and the vasomotor and vegetative trophic disturbances. Follow-up examination five months after operation revealed 1 failure among the author's 6 cases. Although the immediate effect of resection of the sympathetic trunk is quite impressive, the complete denervation of the involved member is advisable in order to avoid relapses. Conservative measures, such as Leriche's anesthesia of the stellate ganglion, should be tried first. The reported microscopic changes indicate that in chronic cases even interventions on the sympathetic will fail.

Cutaneous Relapses After Operation for Cancer of Breast.—Rieks attempted to determine whether cutaneous recurrences of mammary cancer are less frequent after operations with the electric knife than after operation with the scalpel. Gerlach had demonstrated the superiority of the electric knife on the basis of cases treated at the clinic in Breslau between 1928 and 1933. Rieks reinvestigated Gerlach's cases as well as a number of additional cases treated up to 1939. She found that cutting with the high frequency instrument did not contribute to a noticeable reduction in the cutaneous relapses but that the improved roentgen irradiation improved the surgical results, so that the number of cutaneous recurrences was decreased by one third. She thinks that carefully planned postoperative roentgen irradiation will lead to even better results. Electric cutting had the effect that the relapse-free period was prolonged from an average of nine to an average of fifteen months.

- *Jejunal Ulcer and Gastrojejunocolic Fistula. H. von Haberer.—p. 1182.
Guiding Lines in Surgery of Bile Passages. G. Pototschnig.—p. 1190.
A Rare Postoperative Complication. R. Tölle.—p. 1202.
Permanent Cure of Primary Sarcoma of Stomach. I. Maack.—p. 1204.

Jejunal Ulcer and Gastrojejunocolic Fistula.—Gastrojejunocolic fistula is a grave complication of a jejunal peptic ulcer which requires a truly radical operation to overcome it. Von Haberer resects the stomach, including the pylorus and tissue beyond the gastrointestinal anastomosis if an operation for exclusion has preceded the condition, also the excluded part and the fistula bearing segment of the colon. He encountered 25 instances of gastrojejunocolic fistula after 241 radical operations for jejunal peptic ulcer. The incidence of jejunal peptic ulcer can be considerably reduced by avoiding gastroenterostomies, particularly the unnecessary ones, as well as all operations for exclusion.

Book Notices

Clinical Diagnosis by Laboratory Examinations. By John A. Kolmer, M.S., M.D., Dr.P.H., Professor of Medicine in the School of Medicine and the School of Dentistry of Temple University, Philadelphia. Cloth. Price, \$8. Pp. 1,239, with 75 illustrations. New York & London: D. Appleton-Century Company, Inc., 1943.

From the prolific pen of Dr. Kolmer comes another book which will receive a hearty welcome from physicians, students and clinical pathologists. It is devoted principally to the interpretation of the findings of the laboratory and their application to the scientific practice of medicine. In the last three decades the laboratory has assumed a most important role in the diagnosis and treatment of disease not only in the hospital but also in private practice. While the clinical pathologist is frequently called on in consultation to evaluate the laboratory findings, the responsibility finally rests on the clinician, who not only supervises the collection of the specimen but must also correlate the results of the laboratory with the clinical data at the bedside or office. In this volume he will find useful information to guide him.

The work is divided into three parts. The first comprises the clinical interpretations of practically all the tests used in the laboratory, even those of hormones, vitamins and the allergic reactions. Under each chapter heading is a discussion of the underlying physiology as well as its bearing on the treatment. A most valuable feature running throughout the entire volume is the tables summarizing the contents of each chapter in concise wording which should prove a boon to the busy practitioner.

The second part is devoted to the practical application of laboratory examinations in clinical diagnosis and ranges over a large number of diseases, such as those of the blood and the urinary system, the venereal diseases, those of the digestive and cardiovascular systems, diseases of the respiratory tract, those of metabolism, and infectious diseases. Included are also diseases of vitamin deficiency and the endocrine glands. Considerable attention is devoted to the interpretation of serologic tests, particularly those in syphilis, which at times have plagued the pathologists as well as the clinicians. Due consideration is given to false positives and so-called biologic falsely positive reactions. Transfusion hazards and the Rh factor are adequately discussed. The intradermal tests are beautifully illustrated by colored plates. As the mode of collection of the specimen is of primary importance, the cooperation of the clinician is continually emphasized.

The third part deals with the technical procedures of the laboratory tests and comprises 134 pages of short descriptions of various examinations. They are not intended to replace the larger manuals but are inserted here for the convenience of students in medical technology who prefer to have the technic and the interpretation in the same volume. Among the newer tests are those for crystals of sulfonamide compounds in the urine, and the determination of the various sulfonamides in the blood.

The index is quite thorough, the boldface type indicating the important sections. There are a few typographic errors, probably unavoidable in a volume of this size. A bibliography, intentionally limited, is appended to each chapter.

Pathological Histology. By Robertson F. Ogilvie, M.D., F.R.C.P., Lecturer in Pathology and Assistant in Forensic Medicine, University of Edinburgh. Foreword by A. Murray Drennan, M.D., F.R.C.P., Professor of Pathology, University of Edinburgh. Second edition. Cloth. Price, \$9. Pp. 411, with 235 photomicrographs in color. Baltimore: William Wood & Company, 1943.

The revised edition contains an increase of seventy-six pages and fifteen illustrations. The volume is unique in the content of so many color photomicrographs of histopathologic processes. Many improved pictures replace previous photographs and are presented in colors strikingly similar to the appearance under the microscope. Typical special staining reactions as well as pigment deposits and microchemical tests are well portrayed. The color reproductions, however, while excellent, lack the clear minute histologic detail that only black and white illustrations apparently can depict. The text portions are almost limited to short macroscopic and more detailed microscopic description of representative pathologic conditions that usually comprise the slides used in teaching students histopathology in the laboratory.

In this way the book is meant to supplement the average textbook of pathology for the medical student. The first four chapters discuss and illustrate general pathology, the next two tumors and the remaining twelve the special pathology of various systems. The newly added chapter of ten pages on the integumentary system describes two unusual skin conditions and may well have been omitted. The chapters on the histopathology of the kidney, heart, blood and hemopoietic system are particularly instructive. This work can serve as a guide for assistants in the laboratory course of histopathology as well as a reference book for students. It should emphasize the great value of the use of modern Kodachromes in demonstrating cellular changes to students and to practitioners in the clinicopathologic conference.

Medical Parasitology and Zoology. By Ralph Welty Nauss, B.Sc., M.D., Dr.P.H., Assistant Professor of Public Health and Preventive Medicine, Cornell University Medical College, New York. Foreword by John C. Torrey, Ph.D. Cloth. Price, \$6. Pp. 534, with 95 illustrations. New York & London: Paul B. Hoeber, Inc., 1944.

As indicated in the foreword and preface, this volume is designed primarily to meet the needs of second year medical students for laboratory, lecture and collateral information in the field of medical parasitology and zoology. On the whole this goal has been achieved, although the material is not always coordinated, at times is internally inconsistent and abounds in minor technical errors.

The subject is divided into four main sections and in addition contains a group of appendixes, a glossary, a bibliography and a subject index. In each main section, i. e. Protozoa, Parasitic Worms, Arthropods and Disease Transmission, and Poisonous and Venomous Forms, the disease-producing organism is first presented and then successively the epidemiology, pathogenesis, symptomatology, diagnosis, treatment, prognosis and prophylaxis of the disease are considered. The best presentations in the opinion of the reviewer are malaria, trichinosis, hookworms and hookworm infection, and venomous snakes.

Appendixes I-IX contain useful information in making laboratory diagnosis and in preparing material for class use. The glossary is probably too lengthy and too inclusive. The bibliography is divided into two parts, although the reviewer has been unable to discover the reason for this division.

Inaccuracies or inconsistencies of thought or statement include the following: (1) "amebic dysentery" is "characterized by a bloody mucoid diarrhea" (p. 25); (2) chiniofon, anayoden and yatren are referred to as different chemotherapeutics (p. 42); (3) the dosage of these antiamebic drugs is given as "3 or 4 enteric-coated 4-grain (0.25 Gm.) pills or tablets daily," rather than t. i. d. (p. 42); (4) there is no mention of diodoquin, while special emphasis is placed on the value of emetine bismuth iodide; (5) the seatworm (*Enterobius vermicularis*) is referred to as resulting from soil pollution (p. 139); (6) *Echinococcus granulosus* and *Hymenolepis nana* are considered as "food-infesting worms" (pp. 201, 206), and (7) Brill's disease and murine typhus are regarded as synonymous (p. 316).

There are several peculiar spellings and combinations of the technical names of etiologic agents of disease, viz. *Taenias*, *saginata* and *solium*; *Wüchereria* for *Wuchereria* and *malaya* for *malayi*. The section of arthropods is especially subject to criticism because of the numerous technical and orthographic errors in technical names.

Some information is not up to date, especially in the treatment of kala-azar, oxyuriasis, strongyloidiasis, *Fasciolopsis buski* infection and in the present day distribution of yellow fever and *Aedes aegypti*, the yellow fever transmitter.

There are numerous line and halftone illustrations and one beautiful color plate on the malaria parasites. A few of these are original. Some of the borrowed ones are inaccurate and others suffer from too great reduction or from second hand reproduction.

There is unquestionably a large amount of valuable material in this book, but it should not be placed in the hands of the medical student without first giving him a series of mimeographed sheets indicating the more serious errors. The reviewer looks forward to a second edition in which greater editorial care is exercised. The volume is well printed and has a pleasing format, but considerable paper could have been saved with more careful planning.

Medical Clinics on Bone Diseases: A Text and Atlas. By I. Snapper, M.D. Cloth. Price, \$10.75. Pp. 225, with 30 plates. New York: Interscience Publishers, Inc., 1943.

This is a new English edition of the author's well known monograph on a selected group of degenerative bone diseases. It consists of chapters on Recklinghausen's disease, on hyperplasia of the parathyroid secondary to other diseases, on avitaminosis D including fetal, infantile, late rickets and osteomalacia, on Paget's disease of the bone, on the lipoid granulomatosis, on Gaucher's disease and on multiple myeloma. Earlier editions of the author's studies of degenerative bone diseases appeared in the Netherlands and in France in 1938. The chapter on hyperparathyroidism is introduced by the author with a clear and concise historical review. In this he demonstrates his ability to select the high points on the road of our advancing knowledge without being burdensome by overquotations. This same discernment is evident also in his introductory discussions on lipoid granulomatosis and other conditions, especially Paget's disease.

From the diagnostic point of view, one cannot fail to appreciate the section on differential diagnosis; this applies in particular to osteitis fibrosa, to Paget's disease, to myeloma and to carcinomatous metastases. Similar attention is given to the differentiation in osteoporosis and lipoid granulomatosis as well as to renal insufficiency and osteomalacia. There is ample documentation by minute and thorough case reports. The most attractive and instructive features of the book include the pathologic descriptions and the reproductions of histopathologic and x-ray photographs. Roentgenograms and photomicrographs are excellent. While the chapters on osteitis fibrosa, osteitis deformans and vitamin deficiency are the most important because of the frequency of occurrence, the author nonetheless has spent the same painstaking effort on the less extensive chapters on lipoid granulomatosis and xanthomatosis of the bone. All are given concise historical introductions, a clear presentation of the principal clinical symptoms and particularly thorough treatment of the pathologic features. For the pathologist as well as for the orthopedic surgeon, this book is of exquisite instructional value. An English edition of this work is most welcome.

Pathology and Therapy of Rheumatic Fever. By Leopold Lichtwitz, M.D. Foreword by William J. Maloney, M.D., LL.D., F.R.S., Consulting Neurologist to the City Hospital, New York City. Edited by Major William Chester, M.C. Cloth. Price, \$4.75. Pp. 211, with 69 illustrations. New York: Grune & Stratton, Incorporated, 1944.

This is an interesting and unorthodox presentation of the pathology and therapy of rheumatic fever. In thirteen chapters are presented clinical and pathologic observations of rheumatic fever, rheumatic and nonrheumatic arthritis and certain related conditions. The last chapter is devoted to a consideration of therapeutic procedures in these various conditions. There are many excellent illustrations, and a short reference list appears at the end of each chapter. In his charmingly written historical foreword Dr. William J. Maloney gives an excellent summary of the main thesis of the monograph: "In it, Professor Lichtwitz has marshaled his scientific and clinical resources convincingly to present rheumatism as a manifestation of allergy. The antigens, to which he attributes the disease, are all foreign proteins of one sort or another. Some are as exogenous as horse sera; others are products of the proteolysis that tissues undergo when spent or damaged; and others, again, are metabolites of invading micro-organisms." There is much in this little book to stimulate the student of rheumatic fever, and it is certain to find many interested readers.

A Manual of Medical Parasitology. By Clay G. Huff, Professor of Parasitology, University of Chicago. Cloth. Price, \$1.50. Pp. 88, with illustrations. Chicago: University of Chicago Press, 1943.

This is based on the required course in the Medical School of the University of Chicago. The author notes the current need for greater emphasis on this field in the curriculum of medical schools than has been accorded in the past. The war, the shrinkage in the time and distance relations with the rest of the world, the great expansion in travel and the resulting increase in the sources of parasitic infections all combine to increase the importance of this field. This textbook covers the commoner parasitic infections of man, the insect vectors of blood diseases and the microscopic, serologic and immunologic methods employed in their diagnosis. It deals with the pathology but not with the treatment of parasitic infections.

Manometric Methods as Applied to the Measurement of Cell Respiration and Other Processes. By Malcolm Dixon, Ph.D., Sc.D., F.R.S. With a foreword by Sir F. G. Hopkins, O.M., F.R.S. Second edition. Cloth. Price, \$1.75. Pp. 155, with 26 illustrations. New York: Macmillan Company; Cambridge: University Press, 1943.

Dr. Dixon in this edition has assembled expertly and with authority the pertinent literature on manometric methods in the form of a handbook. Since these techniques are now being widely used in biologic research and are being applied to an ever increasing variety of problems, this not too technical account is a distinct service not only to beginners who desire knowledge of the principles involved and errors to be guarded against but also to more advanced workers. Part I deals with the types of manometers. The theory, which can be followed by any one with a knowledge of the gas laws, is given in detail for the constant volume and differential types. Methods of calibration and other practical details are described. Part II gives in detail the methods for measuring respiration, including the direct method, the first method of Dickens and Simer, the indirect method of Warburg, the second method of Dickens and Simer, the method of Dixon and Keilin and micro methods. These are described in a logical sequence which reveals the advantages or shortcomings of each in particular problems and the need of new and better procedures. Theory, when indispensable to an understanding of the procedure, is clearly presented. Many practical details, some of which would certainly be overlooked by the novice, are mentioned whenever the author thought it expedient, and the necessity for many precautions is explained. A few pages on micro methods and some protocols from actual experiments complete the text. Research workers in the field of manometry will welcome this well written and most helpful laboratory manual.

The Dysenteric Disorders: The Diagnosis and Treatment of Dysentery, Sprue, Colitis and Other Diarrheas in General Practice. By Sir Philip Manson-Bahr, C.M.G., D.S.O., M.D., Senior Physician to the Hospital for Tropical Diseases, Royal Albert Dock and Tilbury Hospitals, London. With an appendix by W. John Muggleton, M.S.M., F.I.M.L.T. Second edition. Fabrikoid. Price, \$10. Pp. 629, with 131 illustrations. Baltimore: William Wood & Company, 1943.

The second edition of this medical classic contains the many advances in etiology, diagnosis and treatment of the dysenteries and related disorders which have been developed in the years since the first (1939) edition. The introduction of sulfaguanidine in the treatment of bacillary dysentery is recorded. In view of the recent new light on the cause of the sprue syndrome and the relationship of this symptom complex to the steatorrhea and fat absorption a new chapter on pellagra has been inserted, a better understanding of the complexities of this nutritional disorder having shed much light on the group of diseases with which it has much in common. Mechanized warfare has changed the habits of men but it has in no way lessened the horrors of these diseases, which take a heavy toll of men in combat areas. This war will do much to spread these diseases abroad throughout the world; hence the value of this authoritative and comprehensive treatise in general practice. It is the outgrowth of many years of practical experience in field and hospital by one of the leaders in this important aspect of private practice, public health and preventive medicine.

Pasteurisation. By Harry Hill, F.R., San.I., A.M.I.S.E., F.S.I.A.; Sanitary Inspector, Borough of Southgate. Fabrikoid. Price, 10s. Pp. 152. London: H. K. Lewis & Co., Ltd., 1943.

This volume is well written and the subject thoroughly covered. The writer is thoroughly familiar with his subject. The concise manner of treating the subject and the absence of burdensome, technical detail and statistics serve to make the volume valuable to health officers lacking special training in milk sanitation. The book merits a wide circulation, especially in communities where raw milk is sold. It should also prove suitable as a textbook in medical colleges and nursing schools. Health officers and legislatures are furnished with sound arguments as to the necessity for pasteurization of milk and milk products. The criticisms of opponents of pasteurization are effectively met. The writer's discussions with respect to modern methods of pasteurization of milk, equipment and plant design and the processing of special milk products are well presented. Although the volume treats with problems in England, this fact should render it no less valuable in this country, since the problems discussed are essentially the same.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

MERCURIAL DIURETICS IN NEPHRITIS

To the Editor:—If mercurial diuretics can be safely used in the treatment of edema from chronic nephritis, could favorable kidney function tests, especially urea clearance, be considered as criteria?

F. G. Scovel, M.D., Rochester, N. Y.

ANSWER.—It is doubtful whether mercurial diuretics can be used safely in chronic nephritis. The major indications for their administration are embarrassing accumulations of edema fluid or ascites due to nonrenal causes, such as hepatic cirrhosis, venous obstruction and/or cardiac incompetence. The edema of nephrosis is associated with damage to the convoluted tubules of the kidney; the mercurial diuretics operate largely through impairing the reabsorption of water by these elements, probably by local toxic effects on the tubule cells. Opinion as to the advisability of applying mercurial diuretics in cases of bilateral chronic renal disease is not unanimous. The consensus, however, is to the effect that it is not without hazard. Acute exacerbations of renal injury have been observed.

Favorable renal function test results are suggestive that the mercurial diuretics may be well tolerated. Probably the most useful single test in this connection is the concentration test. The concentration of the urine (specific gravity) is conditioned largely by the functional integrity of the convoluted tubules. Thus, a good response to relative dehydration—specific gravity 1.025 or higher in the Fishberg procedure (Fishberg, A. M.: *Arch. Int. Med.* 38:259, 1926) is indicative of active tubule functioning. The urea clearance test, although, perhaps, more mathematically quantitative, is not as sensitive to early impairment.

There are many other therapeutic methods of attacking edema in chronic nephritis. If due to hypoproteinemia, as it often is, replacement of the depleted serum proteins is indicated. Plasma or whole blood transfusions are often immensely valuable. The xanthine diuretics and acidifying salts (ammonium nitrate, calcium chloride and so on) are often effective and safer than the mercurial diuretics, although the responses are not as dramatic. One must keep in mind that edema fluid is more than merely retained water; it is full of toxic metabolic debris. Too rapid mobilization of intercellular fluid and diuresis are often dangerously intoxicating to a patient already very sick. More gradual reduction is safer. Edema per se in the extremities and loose connective tissue of the body is relatively harmless. One may do more harm than good by concentrating attention on the symptoms and treating the disease rather than the patient who has the disease!

SILVERY LESION OF SKIN

To the Editor:—For approximately a year one of our hospital employees has had a nonpruritic silvery white streaked lesion which resembles scar tissue over the anterior surfaces of the bony prominences of both clavicles. The lesion seems to be slowly spreading. This location would coincide with the neck line of her starched uniform. Would you kindly advise if starch will cause a lesion of this type. If not, what could be the etiology and what do you advise for treatment?

M.D., South Dakota.

ANSWER.—A nonpruritic silvery white streaked lesion suggests several possibilities. By far the commonest of these is linear atrophy of the skin, seen commonly on the abdomen after childbirth. While it is usually thought of as resulting from stretching of the skin, it is also seen in those whose skin has not been subjected to this form of trauma. In many instances it has followed toxic conditions, such as typhoid, tuberculosis or syphilis. The lesions may occur anywhere on the trunk or limbs as narrow lines which are at first brownish or purplish red, later becoming silvery white, slightly depressed streaks which show cross wrinkling. No form of treatment will benefit them. They are scars. A good description may be found in the book by Ormsby and Montgomery (*Diseases of the Skin*, ed. 6, Philadelphia, Lea & Febiger, 1943, p. 492). Direct trauma, such as the rubbing of a starched uniform, is not usually considered important in their causation.

Morphea, localized scleroderma, is not rare and often occurs as band shaped lesions, ivory colored to pure white, often sur-

rounded by a zone of violaceous color. These lesions may occur anywhere on the skin and are at first distinctly infiltrated, later becoming soft and atrophic. They may be slightly elevated or depressed or may be at skin level. Trauma is often suspected of influencing the localization of such lesions, so that the irritation caused by a stiffly starched garment might be of importance. Most commonly they are treated by the administration of thyroid or by roentgenotherapy but so often resolve spontaneously that it is difficult to be certain how much credit the treatment deserves. They may, however, resist all efforts for many months. Boardman (*Scleroderma*, *Arch. Derm. & Syph.* 19: 901, 1929) presents a good discussion of this disease.

There are 2 other remote possibilities. Lichen sclerosis et atrophicus is a rare disease of the skin, considered by Nomland (Lichen Sclerosis et Atrophicus [Hallopeau] and Related Cutaneous Atrophies, *Arch. Dermat. & Syph.* 21:575 [April] 1930) as midway between lichen planus and scleroderma. It appears as light red papules, becoming silvery white with dark colored, depressed puncta, one or several on each papule. The surface is dry and harsh to the touch. While trauma plays an important part in the localization of the lesions of lichen planus, forming linear groups as a response to scratching, no such effect is evident in the rare atrophic disease. The patches are groups of discrete papules or macules in roughly round or oval form. This disease is much less amenable to treatment than is lichen planus.

Pseudoxanthoma elasticum is a rare disease of the skin often associated with angioid streaks of the retina. It occurs as yellowish papules in groups or lines, often on the neck. Recently Silvers and Wolfe (Pseudoxanthoma Elasticum with Angioid Streaks, *Arch. Dermat. & Syph.* 45:1142 [June] 1942) have reported a case in which the lesions in the axilla were "chalk white." This also is a degenerative disease not amenable to treatment and important because of its retinal lesions, which often lead to blindness.

PROBABLE ATYPICAL THROMBOCYTOPENIA

To the Editor:—A woman aged 38 has had attacks of acute bone necrosis, with the local manifestations of a bone infection but without the systemic symptoms that would accompany a true osteomyelitis. Two years ago following a right sacroiliac sprain there developed ecchymoses of the tissues overlying the joint. The joint was painful and swollen, but there was no systemic evidence of infection. The joint was opened, and a necrotic area the size of a quarter (24 mm.) was curetted. Convalescence was complete. One year later the process repeated itself in the tenth rib, left side, anteriorly. A section was resected and reported osteomyelitis. However, growth of bacteria was not obtained and the guinea pig inoculation was negative for tuberculosis. About six weeks ago the left elbow became swollen and discolored, with areas of ecchymosis around the entire joint. Pain and tenderness is severe. A cast was applied, and improvement was noted only to regress to an acute condition shortly after cast was removed. The past history includes cholecystectomy fifteen years ago and cystic mastitis twelve years ago, followed by postoperative hemorrhage. X-ray sterilization was done three years ago for severe menorrhagia and migraine. The migraine disappeared after the x-ray treatment. The patient has had the following medication for many months: 1. Weekly injections of estrogenic substance 10,000 units gradually reduced to 5,000 units. 2. Thirty grains (2 Gm.) of calcium lactate daily. 3. Ascorbic acid 100 mg. three times a day with intramuscular injections of a like amount twice weekly. 4. Adrenal cortex extract 1.5 cc. twice weekly. 5. Vitamin K 2 mg. with bile salts daily. Repeated x-ray examinations of the elbow involved have been negative for a pathologic condition of the bone; the urine is normal; the Wassermann reaction is negative; hemoglobin is 75 per cent; the red blood cell count is 3,790,000; the color index is 1; leukocytes number 8,450, with polymorphonuclear cells 69 per cent, eosinophils 1 per cent, basophils 2 per cent, monocytes 2 per cent and small lymphocytes 26 per cent. The bleeding time was 25 minutes, coagulation time was 8 minutes and blood platelets were 65,000. There was no retraction of clot after five and one-half hours. Is this a case of idiopathic thrombocytopenia and if so what is the best recommended treatment?

Stanley P. Jones, M.D., Mattituck, L. I., N. Y.

ANSWER.—Idiopathic or essential thrombocytopenia rarely is associated with hemorrhages into isolated joints, soft tissues or bones. Purpura is almost a constant finding in thrombocytopenia. The symptoms in this case have occurred over a period of years. The lesions described may have been produced by hemorrhages into subcortical bone or into the joint. The symptoms and findings of thrombocytopenia include (1) purpura, (2) hemorrhage from slight traumas, (3) increased bleeding time, (4) normal coagulation time, (5) absence of clot retraction, (6) decreased capillary resistance, (7) decrease in blood platelets and (8) moderate decrease in hemoglobin or red cell count.

For the patient described several of the findings mentioned have been noted. These include hemorrhage into the tissues, increased bleeding time, normal coagulation time, absence of clot retraction, decrease in blood platelets and a mild secondary anemia. If cutaneous purpuric lesions were ever present they were either not recognized or the description of them was omitted. Although the case would have to be considered atypical, a diagnosis of chronic essential thrombocytopenia would

seem to be justified. If, in addition to the findings described, capillary resistance could be shown to be decreased and repeated examinations of the cutaneous surfaces of the bone should reveal at any time a purpuric rash, the diagnosis could be considered to be confirmed.

It would be advisable to ascertain with certainty that this patient has or has not been intermittently exposed to such toxic agents as benzene, arsenobenzene, quinine or sedormid. Any one of these drugs or chemicals may be the etiologic factor producing secondary thrombocytopenia.

Treatment of thrombocytopenia, in addition to the medication which this patient has already been receiving, might include an occasional blood transfusion, the injection of 20 cc. of the patient's own blood intramuscularly or the intramuscular injection of sterile milk.

The snake venom treatment has been reported both favorably and unfavorably. Moccasin venom is used in a dilution of 1:3,000. An intracutaneous wheal is first made to test for sensitivity, and this will usually be found to be positive. If, following the series of injections, the intracutaneous venom reaction becomes negative, the prognosis may be considered to be more favorable than if it remains positive. Four-tenths cc. of the described dilution of moccasin venom should be injected subcutaneously or intramuscularly twice the first week. The dosage can be increased 0.1 cc. each week until 1 cc. doses are given, provided there is no severe systemic reaction.

If the patient does not improve, and certainly if in spite of treatment the hemorrhagic symptoms become more pronounced, the removal of the spleen will be definitely indicated. About 75 per cent of patients with chronic thrombocytopenia subjected to this operation have made complete or symptomatic recoveries. On the other hand, splenectomy may be attended by severe hemorrhage, shock and death. Only the most highly skilled and trained abdominal surgeons should undertake the operation or removal of the spleen.

JAUNDICE, BAD TASTE IN MOUTH AND POSSIBLE CHEMICAL CAUSATION

To the Editor:—A man aged 38, a construction worker who had never been seriously ill, began to cough a great deal in January 1943 and complained of frequent nausea. At the same time he noticed a peculiar taste in his mouth, which could not be influenced by any means. In February there developed pain in his right chest and he went to bed. The cough continued with the expectation of "thin" mucus, and his general condition deteriorated to such an extent that he was unable to work. He complained then of frequent dizziness and faint spells. He had lost by that time some 30 pounds (13.6 Kg.). After he had gone to bed in February a yellow discoloration of the skin which had been noticed by his friends became more intense. Three weeks thereafter he reports that his gums became dark, almost black, his teeth became brittle after they became "dull" during the early part of his illness, and eventually all his teeth broke off and had to be entirely removed. Eventually the general condition improved, and the patient was able to return to work in June, but up to this time he complained of weakness and soreness in his mouth. The objective findings are essentially negative except swelling and small vesicles of the gingiva. Throughout his illness the patient had not lost the peculiar taste mentioned. In June he discovered accidentally an agent which had the identical taste as that which had bothered him throughout these months, and he found that it was sodium hypochlorite, which was used on his job for sterilizing water containers. The question is now whether this agent could be held responsible for the symptoms of the patient and also whether his illness can be accepted as an industrial accident covered by workmen's compensation.

Gerhard Kersten, M.D., Lycoming, N. Y.

ANSWER.—Many patients with disease states resulting in jaundice complain of persistent abnormal tastes. Any substantial injury from hypochlorite in other than large quantities is almost wholly ruled out through the fact that many hundreds of thousands of soldiers for many years have consumed water treated with such chemicals, and many millions of persons have consumed milk and other foods in contact with utensils and equipment disinfected with hypochlorites and not always under conditions scrupulously accurate as to the quantities of chemicals utilized. Hypochlorites are well known skin irritants in such places as the photographic laboratory and the operating room, in the latter of which hypochlorite solution above 0.5 per cent if used for surgical disinfection may induce skin injury. Lately hypochlorites have been associated with the cause of a minor condition popularly known as "angel eyes," leading to abnormal vision. All considered, no allegation that sodium hypochlorite brought about the condition described in the query may be regarded as substantiated by the facts so far furnished.

The rapid destruction of the teeth suggests the possibility of phosphorus poisoning; the black discoloration of the gums suggests bismuth poisoning or more remotely mercurialism. The key to this case probably is to be found in the type of hepatic disease leading to jaundice. However, the data furnished are

wholly inadequate for the determination of the nature of the jaundice. Without listing the missing essentials, it is apparent that accurate appraisal either of the liver condition or of the chest condition cannot be made.

RECURRENT ATTACKS OF TONIC SPASM

To the Editor:—A boy aged 3½ years was brought to me April 21, 1943 about 7:30 a. m. one hour after his parents had found him in a stupor, his jaws set and his limbs rigid. About thirty minutes before they discovered this condition he had awakened from an apparently normal sleep and had asked for a drink. Before it could be obtained he had dropped off to sleep. He had been perfectly well the day before and had had no previous attacks of any serious illness. After bathing the patient in warm water for ten minutes without any improvement they took him to the hospital. Examination showed that the temperature was 94 F. (checked four times with two thermometers), pulse rate 72, respiratory rate 20. The skin was slightly pale and cold but was dry. He lay quiet and when moved he would moan as if in pain. His eyes were kept shut most of the time. On being opened they rolled up and from side to side and had a glassy stare. The pupils measured 4 mm. and reacted to light. The jaws could not be opened. There was no frothing or bleeding at the mouth. There was no opisthotonos, but there was resistance to flexion of the neck. Both upper extremities were held in rigid flexion. The back and legs were less rigid, but movement was resisted. Examination of the heart, lungs and abdomen was essentially negative. A spinal tap showed water clear fluid and no increased pressure. No protein or cells were found in the laboratory. The only treatment given was application of external heat. In four hours the temperature was normal and the patient began to relax and regain consciousness. By six hours he was taking fluid eagerly and his rigidity and trismus were gone. His stupor gradually left, and in forty-eight hours he was apparently normal. A physical examination at the office six weeks later was essentially negative. On August 14 he had a second attack, similar in every way including the time of day, except that recovery was more rapid. On October 25 he had a third attack, similar in every way except that there was some frothing at the mouth and some clonic movements interrupting the rigidity. This patient is the tenth child in a family of eleven. He has been perfectly well except for these attacks. His diet is average including more than 3 pints of milk daily. There is no history of head injury. There is no known epilepsy in the family. What diagnoses other than epilepsy would you entertain? In what conditions might one find such a low rectal temperature? What studies or treatment would you advise?

M.D., Idaho.

ANSWER.—The case is too complicated and presents so many factors that cannot be explained from the history that exact diagnosis is not justified. Epilepsy might be considered in view of the clonic movements with rigidity and frothing of the mouth noticed on the third attack. The other two attacks, however, are not so characteristic of this disease. The tonic spasm described in the first two spells with setting of the jaw and rigidity of all the limbs, plus the low temperature, suggests a lesion in the region of the hypothalamic centers with a condition known in laboratory animals as "decerebrate rigidity." This is occasionally seen in patients with brain tumors, particularly suprasellar cysts or in hydrocephalus and is a somewhat similar condition to that described by Wilson in 1920. The case here described varies from typical decerebrate rigidity in the flexion instead of the extension of the arms. When rigidity is intense, it is difficult to bring out the tonic reflexes described by Magnus and deKleyn.

The patient requires extensive study. Electroencephalograms should be done and possibly a ventriculogram. These studies can best be carried out in a large center where there is a fully equipped neurologic clinic.

PANNICULITIS RESEMBLING SCLERODERMA

To the Editor:—Does an active panniculitis develop in lesions of scleroderma? Is it possible for a chronic localized form of panniculitis to undergo secondary sclerosis with the development of a scleroderma-like condition?

Samuel Irgang, M.D., New York.

ANSWER.—There are several reports of cases of nodular, non-suppurating panniculitis which at some part of their course resembled morphea.

TSUTSUGAMUSHI FEVER IN THE SOUTHWEST PACIFIC THEATER

MAJOR CHARLES E. AHLM

MEDICAL CORPS, ARMY OF THE UNITED STATES

AND

CAPTAIN JACK LIPSHUTZ

MEDICAL CORPS, ARMY OF THE UNITED STATES

This study comprises some 70 cases of tsutsugamushi fever. Most of the patients resided for a period of weeks to several months in an area which has proved endemic for the disease. This paper represents our observations and the experimentation and study possible with limited equipment while working under field conditions. Should this information serve to stimulate further laboratory experimentation and give the profession a better conception of the military and economic importance of this disease, we would feel our efforts well spent.

Until recently the condition about to be considered has not been given the space it deserves in American medical textbooks, owing in part to our lack of interest from the economic standpoint in many of the tropical and subtropical countries. The advent of World War II has, however, changed the picture entirely. We now find not only the men of allied armed forces but our own men suffering the ravages of this fever in many tropical areas. The total man days lost from this disease have presented a problem. This, together with the great advance in air transportation expected in the postwar period, tends to make the disease one of considerable military and economic importance.

Tsutsugamushi fever is to us a suitable name for the disease here described. Tsutsugamushi has been associated with this particular type of fever in Japan since 1899. The name means "dangerous bug fever," which, although it gives no indication of its relation to the typhus group of fevers, is entirely adequate. A comparison of tsutsugamushi fever in Japan with rickettsial fevers as reported from Sumatra, Malaya, New Guinea and other territories under names such as Sumatran fever, K typhus, scrub typhus and Kedani disease shows

a high degree of similarity. Although it has not yet definitely been proved, these diseases appear to be identical. Minor differences might be explained on the basis of the change in virulence of the organism in different localities.

For reasons of military security, we are unable, at the time of this writing, to state our exact location in the tropics.

EPIDEMIOLOGY

Sambon¹ stated that the association between mites and disease has been known for over a thousand years. Tanaka² attributed the "river fever of Japan" to a minute red mite locally called Kedani mite.

There is reasonable evidence to indicate that the cases as reported from Formosa, Korea, Sumatra, India, Malaya, New Guinea and more recently North Queensland, Australia, are probably the same tsutsugamushi fever originally described as occurring in Japan. The pseudo-typhoid as reported by Schüffner³ we believe to be a mild form of tsutsugamushi fever. A low death rate, lymphocytosis and general distribution of rash are not sufficient differential points. The virulence of the micro-organism unquestionably varies in different localities and probably accounts for Schüffner's findings.

The endemic nature of this disease is well known. The majority of our cases occurred in an area of about $\frac{1}{2}$ square mile at an elevation 100 feet above sea level. The annual rainfall has varied from 100 to 120 inches, the highest level occurring during the months of December, January, February and March. It is terrain which is a favorable habitat for rodents; the condition of the ground and type of vegetation are ideal for the larval mite.

Our patients for the most part gave histories of having been in wooded sections, logging or clearing areas where the vegetation is dense. In the process, many contracted the disease. This type of history is quite typical and coincides with the observations of Heaslip⁴ as described in his report from the West Cairns area of North Queensland.

Sufficient time has not yet elapsed to evaluate fully the seasonal factor. It is doubtful, however, that the season will be of any consequence in this particular territory.

The characteristic regional habitat is the scrub along the small streams and areas of dense damp jungle. We also found mites to be prevalent near the sago palm

Major Ahlm was formerly instructor, MRTC, Camp Grant, and at present is flight surgeon with a unit of the AAF.
Captain Lipshutz of the staff of Jewish Hospital, Philadelphia, on leave of absence, is at present assigned to the medical service of a station hospital.

Major Charles L. Garcia, commanding the station hospital, permitted us to review the clinical records in these cases. Capt. R. N. McCulloch of the Third Australian Mobilization Entomological Section gave suggestions and assisted in identifying several specimens of acarina. Drs. K. F. Maxey and F. G. Blake of the American Typhus Commission gave constructive criticism and suggestions. Professors Harvey Sutton and J. W. Fielding of the School of Tropical Medicine, University of Sydney, collected and forwarded Dr. Gunther's papers. Major Markle donated the photographic illustrations. S/Sgt. Norman W. Ibbotson and T/5 Max Davis, Medical Department, U. S. Army, gave much of their free time to typing the manuscript.

swamps margined by kunai grass. Where the kunai grass grew tall in natural clearings adjacent to the jungle, only occasional mites could be found.

ETIOLOGY

A number of early investigators proved the rickettsial nature of this disease, although the specific rickettsia producing tsutsugamushi fever is a matter in which

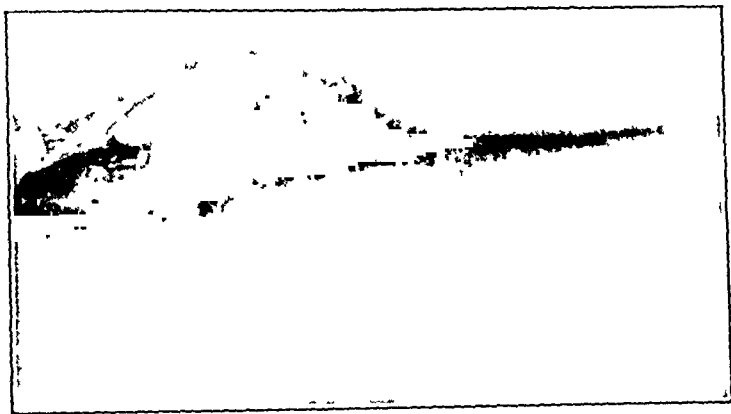

Fig 1—Regional lymphadenopathy.

there is some difference of opinion. It is possible here only to state briefly the findings of a few early investigators.

Hayashi⁵ was first to call the organism causing tsutsugamushi fever in Japan the *Rickettsia tsutsugamushi*. Kawamura and Imagawa⁶ identified the organism as *Rickettsia akamushi*. Sellaris⁷ proposed the name *Rickettsia nipponica* for it. Ogata⁸ confirmed the findings of Hayashi, naming *Rickettsia tsutsugamushi* as the etiologic agent. Reasonable proof exists that these organisms are identical. Lewthwaite and Savor⁹ by means of elaborate and exhaustive cross immunity experiments showed the similarity between scrub typhus and Japanese river fever both by intraocular and by intradermal reactions in rabbits and monkeys. In cross protection tests between the organisms of Sumatran fever and the tsutsugamushi of British Malaya performed on rabbits and monkeys it was the conclusion that these are also identical diseases.

The difficulty of demonstrating rickettsias in human tissue sections is common knowledge, and to date we have been unable to do so. In the future, if the laboratory is able to demonstrate rickettsias in the tissues of cases which come to autopsy, the morphologic characteristics should coincide in a general way with the description as reported by Hayashi.

Hayashi's description will serve to exemplify the typical rickettsial micro-organism producing the disease. He reported a minute rod or spheroid body demonstrable in the cytoplasm of lymphocytes and endothelial phagocytes of the tissues of the local lesion, lymph nodes and spleen, using Giemsa's stain. This he classified as *Theileria*, but it has since been classified with the genus *Rickettsia* (*R. tsutsugamushi*).

Dr. Fielding¹⁰ has kindly consented to attempt the demonstration of rickettsias in some of our arthropod

specimens, using his Modified Breinl method. At a later date we hope to report the results of this experiment.

THE VECTOR

The larval form of the mite genus *Trombicula* is to date the only mite known to be definitely associated with tsutsugamushi fever. Several species of *Trombicula*, and even variants of one species, may be vectors in different localities.

The eggs of the genus *Trombicula* are laid in clusters in the soil several inches below the surface. Here the ova hatch, later passing through the various developmental stages to the adult form. The larvae are small, microscopic, six legged creatures which move about on the ground or herbage until able to attach themselves to a passing host. Rodents, marsupials, birds, bush fowl, lizards or man may provide the blood meal for these larval mites. The nymph and adult probably feed on vegetation, but little is known of their habits.

The rickettsial infection transmitted by the larval mite is apparently inherited from the parent, the larvae not feeding a second time.

Trombicula akamushi was found to be the vector of this disease in Japan. Walch and Keukenschrijver¹¹ reported *Trombicula deliensis* to be the vector in the Dutch East Indies, and Gunther,¹² working in New Guinea, named what he thought at that time was a local variant of *Trombicula deliensis* and called it *Trombicula vanderghinstei*. It is highly probable that *T. akamushi* and *T. deliensis* are at most variants of the same species.

We have collected specimens of *Trombicula* and *Gnatharana* and occasional ticks about the ears and genitalia of field rats and mice killed in this locality. Other specimens, including *Trombicula minor* and *Trombicula fletcheri*, were obtained by standing in a selected area of tall grass or vegetation where the mites would readily crawl on the footgear, being easily removed with the aid of a small camel hair brush. Specimens were placed

Fig 2—Primary lesion

in 70 per cent alcohol temporarily, then mounted on slides for identification. All the specimens we have seen were prepared by the use of Berlese's modified

medium.¹³ Capt. R. N. McCulloch mounted and identified some of our specimens; several were also sent to a laboratory of microbiology and pathology.

Specimens of *Trombicula* are numerous in this area; but the determination of the specific species or variants is extremely difficult, since so many species have already been classified. Until we have completed further laboratory work it is impossible for us to state with accuracy the specific species of *Trombicula* responsible for the fever in this area. We are highly suspicious at this time of three species: *T. minor*, *T. deliensis* and *T. fletcheri*, or perhaps even variants of these species may be responsible for our series of cases. Although ticks (*Dermacentor andersoni*, *Dermacentor variabilis*, *Rhipicephalus sanguineus*) transit other rickettsial diseases, none have as yet been proved vectors for *Rickettsia tsutsugamushi*. The possibility, however, must be considered as new varieties are found and classified.

Trombicula larvae attack regions of the body about the waistline, the scrotum, groin and armpits. It appears to be where the degree of moisture is favorable. The pressure of the clothing is important only because it would tend to increase the moisture of the skin where pressure exists.

In areas a considerable distance from our camp site we have found many mites of genus *Schongastia* and *Neoschongastia*. These are apparently the cause of the common tropical ailment known as scrub itch.

THE RESERVOIR

A previous worker reported natural infection in rats and bandicoots. A series of titers were accomplished on blood from rats trapped in the North Queensland area of Australia. He extracted blood by intracardial puncture, testing by OXK and OX19 agglutination with positive titers (OXK) and in a high percentage of the rodents. We are endeavoring at present to confirm his findings using specimens collected here and will report our findings in a subsequent paper.

Ectoparasites have been removed from the ears and about the genitalia of rats trapped in our area, as previously stated. Many of these were specimens of *Trombicula*, the species of which were quite varied. Several specimens of *Guntherana* were also removed from the rodents. It is our opinion that the field rat is the principal reservoir in this region, the others being of lesser importance.

Gunther lists some seventeen hosts of the larval mite, including the bush fowl, swamp hen, parrot, rat, bandicoot and wild pig. We cannot agree with Gunther in excluding lizards as hosts of the larval mites, since we found numerous larval mites attached to lizards in this vicinity. We were not able to identify the occasional ticks recovered.

CLINICAL REPORT

The most common location of the primary lesion of this disease is the scrotal area, though the inguinal and ankle areas are frequently involved. After an incubation period of seven to fourteen days, the patient complains of headache (frontal), generalized aches and pains, backache, weakness, insomnia, chilliness and fever. A small number complain of pain in the abdomen, with associated nausea and vomiting and occa-

sionally diarrhea. The ulcer varies in size from a few millimeters to 1 centimeter in diameter. Characteristically, a central black necrotic area develops, surrounded by an indurated red areola. Rarely a lymphangitis can be observed tracing its way to the local lymphadenitis. These glands are usually enlarged to the size of a walnut, smooth, tender and not attached to the adjacent

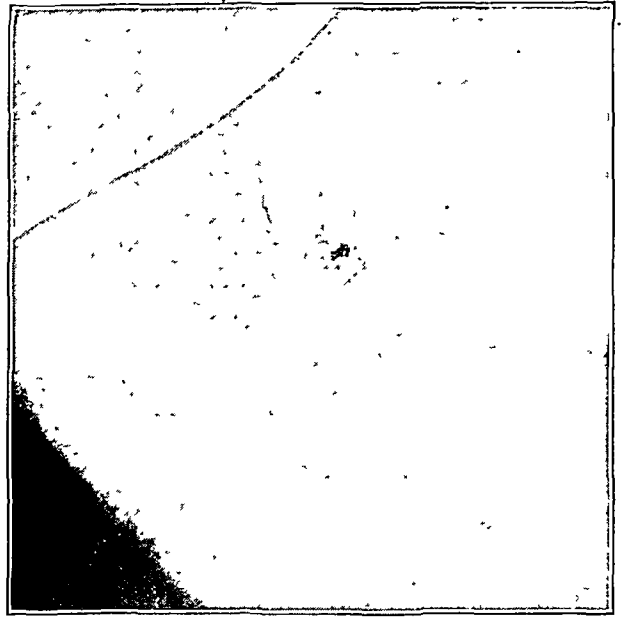

Fig. 3—Primary lesion.

glands or tissues. They do not suppurate. Few cases show a generalized lymphadenitis. The adenitis appears from three to four days after the onset of symptoms. The temperature rises slowly, reaching a peak of 104 or 105 F. within ten days. The pulse is slow in proportion to the temperature rise. A conjunctivitis with mild edema of the eyelids is present. A dusky flush is seen in many instances on the face and neck. As the disease progresses the patient becomes weaker and a generalized myotonia becomes more pronounced. About the fourth day after the appearance of the adenopathy a macular erythematous patchy rash can be observed over the face, chest and abdomen, many of the described areas having a pale raspberry-like appearance. At the height of the disease about 67 per cent of the patients show severe atypical pneumonic signs, with a dry cough and scanty expectoration, and complain of dyspnea and tightness over the sternum. In a few cases there is evidence of consolidation. X-ray examination of about 20 per cent of these cases showed an atypical virus-like pneumonia. Epistaxis was also found in about 20 per cent of our cases and came on at the height of the rise of temperature. Conjunctival hemorrhage has been present in a few cases. Abdominal distention with nausea and vomiting was present in about 60 per cent of our cases and made treatment a difficult problem. About 34 per cent of our cases showed auditory disturbances from mild diminution of hearing to almost complete deafness. Cerebral typhoidal signs are present in many cases, with hallucination, disorientation, insomnia and nervousness being the outstanding features. The elevated temperature continues for ten to fourteen days, during which time the patient is extremely weak and perspires profusely. Myocardial damage has been observed late in the disease, in 3 cases manifested by

13. Modification of Berlese's medium used for the mounting of *Acarina*:

Distilled water.....	100 cc.
Chloral hydrate.....	50 Gm.
Gum arabic.....	40 Gm.
Phenol.....	50 Gm.
Glucose syrup.....	10 Gm.
Glacial acetic acid.....	20 cc.

gallop rhythm, reduplication of the mitral first sound and muffled apical sounds. These are poor prognostic signs and were present in the one death that occurred. The rash usually disappears in from three to five days. The temperature falls by lysis, and convalescence is

agglutination. Many patients with a high titer are mildly ill. We have found that nearly all patients with a low titer showed no primary ulcer. Whether this is due to a different or to a weaker strain of *Rickettsia* remains to be proved.

long. It has been our experience that the white blood cell count is of little diagnostic value, though more than a few cases show a leukopenia with a relative lymphocytosis. The specific agglutination test OXK is negative early in the disease and continues the same through the height of the fever, becoming positive about the second week of the disease. A few cases never become positive. We have not been able to form any correlation between the degree of morbidity and the titer of

PATHOLOGY

In this disease we were able to find no distinctive gross pathologic changes aside from the characteristic cutaneous lesion and enlarged regional lymph nodes. The picture in general is one of visceral congestion. We observed in the heart some petechial hemorrhages through both the pericardium and the myocardium. The cardiac musculature also was quite pale in appearance. The spleen and liver were slightly enlarged. The lungs

exhibited a patchy consolidation similar to an atypical pneumonia. In the brain there was evidence of a vaculitis in the pons and medulla.

DIAGNOSIS

The diagnosis of this condition should not be difficult. In many instances the history will be extremely helpful, the patient having been logging or having cleared sections where vegetation is dense. The endemic nature of the disease, together with the characteristic initial lesion, the regional lymphadenopathy, typical rash, presence of OXK and absence of OX2 and OX19 should prevent error. Mouse inoculation, using blood of the infected patient, and later demonstrating rickettsias in a smear made from pleural effusion, can be used to affirm the foregoing and differentiate the disease from Rocky Mountain spotted fever and typhus.

Typhoid can be excluded by the history, absence of the primary ulcer and the type and time of appearance of the rash, together with the positive Widal agglutination. In plague there rarely is a primary ulcer, the disease is typically epidemic, and the bacillus may be removed from the blood or sputum. The history of rat bite, the relapsing type of fever, leukocytosis, the characteristic rash, the recovery of the spirillum and absence of OXK will differentiate this condition from rat bite fever.

TREATMENT

The most important factors in the treatment of this condition is, in our opinion, absolute bed rest and adequate nursing care, following the line of symptomatic treatment. Acetylsalicylic acid has been found adequate in the control of the severe headache. We discontinued the use of codeine, for in many cases it led to an abdominal distention which interfered with food intake. Fluids and fruit juices are forced (*ad libitum*). Alcohol sponges, enemas and ice caps to the head are used to control the temperature, but apparently nothing has any effect in keeping it down. It has been reported by another group (Australian) that a fall in blood chlorides associated with a fall in blood pressure takes place. We have not been able to affirm this finding as yet owing to the field conditions under which we are working, though we attempt to maintain the chloride level by the oral administration of sodium chloride tablets. Under the regimen we find that the blood pressure remains stable though below normal. We do not feel that the sulfonamide drugs are of value in treating this condition. A number of our patients showing pneumonic signs were given sulfadiazine in adequate doses with no visible effect on the temperature, the duration or the pathologic changes in the lungs. Abdominal distention with nausea and vomiting was the most difficult problem with which we had to contend. Because of the myocardial pathologic condition, a perivascular infiltration of lymphocytes and monocytes throughout the cardiac musculature, we feared giving large doses of saline solution and dextrose by vein. Fifty cc. of 50 per cent dextrose given every four to six hours, in several cases, seemed to be tolerated well. A mild degree of dehydration does not appear to affect the course of the disease. If fluids must be given parenterally, hypodermoclysis is the method of choice. The vitamin need is important both in the active and in the convalescent phase of the disease. Vitamin B complex should be given, supplemented with large doses of multivitamin capsules. Digitalis when given in these cases showing signs of beginning cardiac failure seems to have no effect on

the rate or the rhythm, nor does it affect the outcome in any way. The role of oxygen in the treatment of this condition is overrated. We believe that the dyspnea is due to a venous stasis and a myotonia of all the muscles involved in respiration plus possibly a central respiratory depression. Anxiety and fear play also a major role in this phase of the disease. We have found that with reassurance and sedation this phase subsides. The use of sedatives cannot be overemphasized. Enough must be given to stop the nervousness and allay the anxiety as well as to insure adequate rest. Some clinicians have used lumbar puncture for relief of the cerebral symptoms, but we have found no indication for its use. The use of convalescent serum occurred to us on many occasions, but we feared its use for two reasons: 1. We do not know when the blood stream of the convalescent is free from rickettsias. 2. Would the patient stand the shock of its use? We could not attest the value of immune serum, for we had none. The importance of this disease can be realized only when one examines the facts. Malaria lends itself to treatment readily and has an exceedingly low mortality rate, with only about fourteen man days lost. Tsutsugamushi fever, on the other hand, lends itself to treatment very poorly and has a fairly high mortality rate (considering other figures), with at least one hundred man days lost.

Understanding these facts, the seriousness of the problem cannot be overlooked.

PROPHYLAXIS

We have no information at this writing that inoculation to prevent tsutsugamushi fever in man has proved to be of value. Vaccines from the other rickettsial fevers have had no appreciable effect as a prophylactic measure. The prevention of this disease is largely one of individual protection, the use of insect repellents, proper clothing and the adequate preparation of the site to be subsequently occupied by troops.

The present type of warfare calls for rapid movements of large bodies of troops. This tends to favor exposure to this disease. We advise strongly that where possible areas to be occupied by troops for even short periods be adequately cleared of grass and vegetation by advance details. Natives are often able to give valuable information concerning the conditions in any specific area and should be engaged to assist in preparing the camp site. Troops if possible should employ native labor for any logging required in the construction of buildings.

The camp site is best prepared by cutting and then burning the entire area. This assists in destroying the favorable habitat for infected rodents, and while it does not guarantee destruction of mites it permits the sun to dry the ground sufficiently to produce unfavorable conditions for their existence. Needless to say, the use of rat poison to control the rodent population is necessary.

Troops passing through areas where the disease has been known to occur should at no time be permitted to sleep on the ground. Among paratroops this may become a difficult problem. The use of a hammock of simple construction and of a light weight might prove a solution. In permanent and semipermanent camps, sleeping quarters should be elevated to 4 feet off the ground. Where possible, spraying of the infested ground with a petroleum emulsion is highly advisable.

For individual protection the socks and lower portion of the trousers should be treated with repellent. Apply a small quantity, sufficient to wet the palmar surface of

both hands, then smear over socks and an area up to 6 inches above the trouser cuffs. A high boot or footgear can then be pulled on over the socks. Dusting the body with equal parts of sublimed sulfur and talcum is also recommended.

We have found in a series of experiments that the repellent now in use by the U. S. Army is highly satisfactory if properly applied. The secret of most repellents is knowing how to use them. In our series of experiments to determine the effect of commonly used insect repellents on larval mites it was found that larval mites will not pass through the ordinary khaki uniform worn in tropical areas. The mites will, however, penetrate the mesh of the standard issue wool socks but their progress is greatly deterred. With the treated sock, the arthropod is dead before being able to pass through the sock to the skin. Repeated lectures and demonstrations on the use of repellents by the individual unit are of great value, emphasizing also the need to follow each day's work by a thorough soap-up and shower or bath.

The use of the much talked about mite proof suit as devised by Hayashi and Nagayo appears costly and impractical. The use of solution of sulfurated lime to bathe the parts of the body exposed to mite bites has been suggested by other workers, but we have had no experience with it.

AMERICAN RED CROSS BLOOD DONOR SERVICE

MAJOR EARL S. TAYLOR

Technical Director, Blood Donor Service

MEDICAL CORPS, ARMY OF THE UNITED STATES

AND

MARY E. HEISS, M.D.

Assistant to the Technical Director, Blood Donor Service

NEW YORK

The American Red Cross Blood Donor Service is the sole agency through which the men and women of this country give their blood to the Army and Navy for the preparation of plasma and serum albumin. From its inception in February 1941¹ until Nov. 1, 1943 the Blood Donor Service has collected almost 5,000,000 pints of blood. The service has undergone enormous expansion during the past year in order to accomplish this production. In a project of such scope dealing with so many individuals from coast to coast, it is only natural that all phases of its operation are, and should be, continually before the professional and public eye. This, in effect, is a report concerning the activities of the service, both from the medical and from the statistical point of view.

SCOPE

The American Red Cross Blood Donor Service at present is undoubtedly one of the largest controlled medical projects ever undertaken. As the service looks forward in the next twelve months to continuation of the present scale of activity, it will probably approximate in numbers the large inoculation and vaccination programs. At present thirty-five blood donor centers are in operation in the larger cities of the country.² Their work is augmented by sixty mobile units, which operate from these centers and extend their activity

to seven hundred and eighty additional cooperating chapters of the Red Cross. Through their combined activity they reach approximately 45 per cent of the estimated population of the country. During the past six months between 95,000 and 110,000 donors have appeared each week either at the centers or on mobile unit stations. Considering the age limits and the health standards imposed, and with allowance for those in the armed services, the program would require that 1 out of every 4 persons in the areas covered by the Blood Donor Service would have to contribute a pint of blood within the next twelve months to maintain the program. As will be seen, actually the present rate of redonations is such that this vast coverage will not be necessary.

TECHNIC AND EQUIPMENT

The fundamental conception of the bleeding technic as previously described remains the same.³ However, with increased efficiency gained by experience in the service, production per doctor and nurse has greatly increased. This has been made possible by the untiring efforts of a vast number of Red Cross volunteers, many of whom have devoted as much time to the project as the full time paid personnel. The 100,000 donors who appear each week to give blood are examined and cared for by 129 physicians and 911 nurses. This concentration of professional services has been accomplished only by insistence on full time personnel to carry out the essential procedures and by the transfer of as much responsibility as is compatible with safeguarding the donor—first from doctor to nurse and second from nurse to nurse's aide and other qualified Red Cross volunteers. Eighty per cent of the physician personnel has been provided by the Army and Navy. These medical officers are either on limited service or have a temporary disability that makes them unsuitable for the time being for combat duty. The centers have adopted the same general plan of moving the donors on an assembly line basis, and all employ the open bleeding room arrangement. In this way 2 donors are cared for by 1 nurse, and the entire room can be overseen by a single physician. The appearance of the centers, on an overall appraisal, is essentially the same.

The bleeding bottle is identical with that previously described¹ and has proved satisfactory in this greatly enlarged operation. The actual bleeding technic is the same and follows in detail that originally outlined.³ The safety and efficiency of this technic are borne out in the statistics to be noted.

STANDARDS

As stated originally, the first consideration of the service has always been the protection of the donor.⁴ This has been effected by a carefully controlled basis of operation and uniform technic, and by a rigid adherence to donor standards and requirements. There has been little fundamental change from the donor requirements as originally set forth.³ Minor changes⁵ have been adopted on the basis of experience and mainly cover unusual situations that have come up in dealing with such a large number of donors—approximately 2,000 per working hour throughout the country.

During this calendar year no donors have been accepted who have a history of jaundice in the preceding six months. This stipulation was considered

1. Taylor, E. S.: Blood Procurement for the Army and Navy, J. A. M. A. 117:2123 (Dec. 20) 1941.

2. All statistics are based on thirty centers, as three have until recently produced liquid plasma jointly with the United States Army, and two were opened in January 1944.

3. Taylor, footnotes 1 and 4.

necessary because of the possibility that a virus of "infectious jaundice" might be transmitted through plasma.⁶ Interrogation of 3 million donors appearing for examination during this period indicated that only 325 gave such a history. A compilation of such information is of interest from a public health standpoint in the areas in which the service operates.

COMPLICATIONS

The final test of the efficiency of the standards employed and technics used is the incidence of complications and accidents, coincidental and otherwise, that occur in the donor population. There is a considerable amount of self selection on the part of the donors which in itself militates against many complications. Rather consistently since operations began, from 8 to 8.5 per cent of the donors have been refused because of some variation from the standard requirements. In the selected group which remains, the number of complications and accidents encountered, particularly those of a serious nature, has been far below normal expectancy. There have been no fatalities in or about any of the centers or their temporary mobile unit stations. Of the eight cardiovascular accidents to donors that have occurred in the centers, not one has been fatal.

Although statistical evidence and compiled data are essential in evaluating the safety and protection factors, the donor's own impressions and reactions to the procedure and its effect on his or her well-being are even more significant. In a study over a three month period it was found that 47 per cent of the donors throughout the country were redonors, many of these coming in for their fourth or fifth donation. This implied endorsement by a large number of donors is further documented⁵ in a postcard follow-up on 39,642 donors at four centers, in which a response was obtained from 68.2 per cent. Eighty-one per cent of the group which responded registered no type of complaint. Of the 19 per cent making some comment, only 4 per cent noted anything more than a transient effect, either generally or with reference to the site of the venipuncture. The most informative figure obtained was that only 0.1 per cent of this group had experienced delayed syncope.

The occurrence of delayed syncope is of particular concern when the donor services operate in industrial plants. It is for this reason that no donors who work with or about any type of heavy machinery are bled unless an eight hour interval will elapse before they return to work. In order that this may be carried out, many groups can be reached safely only by having a mobile unit go to the plant when the donors come off shift. Evidence regarding the safety of blood donation in industry has been presented in a general survey by the Industrial Hygiene Foundation.⁷ In a large heavy industry plant, with a population of some 82,000 workers, 39,250 pints of blood has been taken without any record of a serious accident and no evidence of absenteeism or lag in production. The redonor rate in this plant is nearly 40 per cent.

INVESTIGATION

The scope of the project has offered a unique opportunity not only to obtain statistical information but also to evaluate a number of medical problems. Such investigations have in general come under two headings: (1) the donor and (2) the final product, plasma or its by-products.

1. *The Donor.*—(a) Positive Serologic Reactions: The incidence of positive serologic reactions to date has been 0.32 per cent, or 15,197. This low incidence is accounted for in two ways: (1) the high percentage of redonors and (2) the selection on the part of the donors themselves. All instances of positive serologic reactions are followed up, preferably through the donor's own physician, both to fulfil the public health obligation incurred and to perform a service to the donor, who is usually not cognizant of the existence of this condition.

As the number of redonors has increased, a significant number of positive serologic reactions has been reported on donors who already have given blood several times and in whom the previous serologic tests have been negative. This problem is being thoroughly investigated.⁸ It would seem from preliminary results that there are several possible explanations, of which two are of major interest: (1) that repeated donations of blood reactivate an old treated or latent syphilis (provocative reaction); (2) that a change occurs in the globulin or other fraction of the donor's serum after repeated bloodletting which will result in a "false positive" reaction.

(b) Hemoglobin: The Tallqvist method of hemoglobin determination has been standard procedure for all centers. This method was selected on the basis of previous experience with donor groups³ as well as for its speed and simplicity. However, in a project of this size it was felt that the donors should be further safeguarded by checking this type of determination with other methods, e. g. photoelectric cell colorimeter (Evelyn) and the recently developed copper sulfate specific gravity method of Phillips and his collaborators.^{8a} As a result of these studies a modification of the latter method has been adopted for general use in the centers.

(c) A recent article by Master, Marks and Dack⁹ raised some interesting questions with regard to "normal blood pressure," particularly in the age groups over 40. In collaboration with these authors a study is now being made on approximately 25,000 donors to obtain further information on some of these questions.

(d) Syncope: Syncope and the various phenomena associated with it present a continuous and complex problem to the Blood Donor Service. Consistently throughout the country there is some form of "reaction" in 4 to 6 per cent of the donors. Considerable interest has been evinced both in this country and in Great Britain with regard to "fainting in blood donors."¹⁰ but there has been to date no satisfactory evidence presented that has explained this phenomenon in all its variations.

There is a critical amount of blood which can be withdrawn from the healthy adult.¹¹ After approximately 1,000 cc. of blood has been taken, syncope and other striking vasomotor changes will occur in most persons. However, this does not explain either the number of syncopes that occur when no more than 200 cc. has been withdrawn or those that occur when the finger is pricked to obtain blood for a hemoglobin determination. In an attempt to appraise this problem, a questionnaire survey was undertaken on 5,030 donors, 2,292 of whom had some type of vasomotor reaction; the remaining 2,738 were utilized as controls. An effort was made to obtain information on all the possible factors that are thought to be conducive to syncope, either directly or indirectly. The findings were tabulated on punch cards, and the following general impressions were gathered:

Females react more frequently than males by a ratio of 1.5:1. Young persons, particularly females under 21, are apparently more susceptible than those in later adult life. These reactions, however, are mild and transient, whereas the more severe reactions occur in the upper age brackets. Both males and females in the so-called white collar class show a higher proportion of reactions than those in the more physically strenuous occupational groups. This is in general agreement with British findings.¹⁰

The incidence of reactions is four times greater among first donors than among redonors. This is to be expected, as first time donors are not solicited to return if they have had a reaction at the time of their first donation. A history of fainting invariably predisposes to syncope. Donors are often loath to admit to this on routine interrogation, and such a history can often be elicited only after the donor has experienced syncope.

Apprehension on the part of the donor seems to be one of the most important factors in predisposing the otherwise acceptable donor to syncope. The question of the relationship of this factor to certain psychosomatic features of the donor is difficult to evaluate but offers a most promising field of investigation. It is hoped that this preliminary study will serve as a basis for a detailed investigation of the more suggestive causative factors.

There are two forms of reactions that are encountered from time to time which are of particular interest:

1. A small number of donors develop tetany with carpopedal spasm and positive Chvostek and Trousseau's signs. It has been suggested that this may be due to hyperventilation and/or a calcium-phosphorus imbalance.¹² No studies have been done on this group, but in a number of instances hyperventilation has been observed prior to the onset of tetany. Empirically, some of these donors have been treated with carbon dioxide and others with calcium lactate intravenously. Response to treatment has been very striking in some cases; in other cases recovery can hardly have been attributed to the therapy.

2. The other, and equally disturbing, group consists of those donors who have convulsions. This phenomenon, which occurs in less than 1 per thousand donors, has been encountered in almost every step of the procedure. A number of these donors, on further interrogation, have admitted to previous "fits" or con-

vulsive states occurring usually many years before, with no history of such phenomena in the interim.

In order to evaluate this group further, Walter¹³ of the Boston center and Moore¹⁴ of the St. Louis center did encephalograms on a number of these donors. In the 8 tested by Moore, no significant data or information was obtained. In four of the series of 28 investigated by Walter, the encephalograms suggested the typical pattern of subclinical epilepsy, but the findings were not conclusive.

2. *Plasma and Its By-Products.*—(a) The red cell residues remaining after the withdrawal of the plasma-citrate mixture are now being more extensively used.¹⁵ Not only are these residues distributed for use in Army and Navy hospitals, but they are also being offered without cost for clinical investigation to some civilian hospitals that are in proximity to the various processing laboratories.

A considerable number of red cells have been diverted to the production of human peptone for use as culture mediums.¹⁶

Use of red cell residues, both in the liquid and in the dried state, to promote the healing of indolent wounds and ulcers has been reported.¹⁷ Circumstances have prevented any study by this service of the use of the red cells in this manner.

(b) The question has been raised as to whether or not pooled dried plasma can cause reactions because of the agglutinin titer of the pools.¹⁸ To evaluate this question, agglutinin titers have been done on several thousand pilot samples from pools of plasma which have been prepared for the Army and Navy. The samples were chosen at random at each of the processing laboratories. The results of these studies are reported in a separate paper.¹⁹ A standard method of agglutinin titration has been developed which may enable the various workers in this field to make their reports regarding titration comparative.

RESULTS

From Feb. 3, 1941 to Nov. 1, 1943 prospective donors have offered to give blood 5,259,115 times; 4,162,483 of these donors offered to donate within the past twelve months. This represents, on the basis of the number of redonors, approximately 2,500,000 individuals. From this donor group 4,762,308 pints of blood has been obtained; 418,080 donors have been either permanently or provisionally (upper respiratory infection and so on) rejected, a rate of 8 per cent. This rejection rate is uniform throughout the country and varies little with the season of the year. In 78,727, or 1.6 per cent. of the donors accepted, the bleeding team has been unable to obtain blood. It should be noted that no accepted donor is turned away without at least one attempt to obtain blood, no matter how unsuitable the veins appear to be.

Taking into consideration the average hematocrit reading and the 50 cc. of 4 per cent sodium citrate con-

tained in the bottle, most of which is drawn off in the supernatant plasma, it would be ideal to obtain one finished unit of plasma (300 cc.)²⁰ from each full bleeding (550 cc.). Considering losses from all sources—breakage, positive serologic reactions, hemolyzed and clotted samples, material denatured because of breakdown in the drying process—the ratio of bleedings per finished package of plasma since the beginning of the project is 1.079:1. Total losses from contamination are 1.12 per cent; the loss from mechanical defects, i. e. breakage and processing breakdowns, 1.35 per cent; positive serologic reactions, 0.32 per cent. This makes a total loss of 2.77 per cent, or a ratio of 1.03:1. However, this figure presupposes that every bottle delivered to the laboratory contains 550 cc. and leaves no provision for sterility samples and filling losses, which are accounted for in the final ratio. It may be stated that the occasional outbreaks of contamination which occur can usually be attributed to some oversight in the sterilization of the donor sets, pooling bottles or filling apparatus at the laboratory.

Except for the breakage of bottles as they arrive with whole blood, the aforementioned "losses" are actually losses in only a relative sense. A large amount of the contaminated material contains only a relatively small number of organisms and may be salvaged for use in the albumin program if the organisms are not pyrogen formers. Other material is used for moisture samples and the like, so that in reality only the smallest fraction of the amount of blood donated is lost.

Of the blood collected, approximately 4,000,000 bottles have been used in the production of dried plasma for the armed services. Approximately 788,000 bleedings have been employed in the human serum albumin program. Delivery of the finished product parallels the rate of receipt of the whole blood.

In the latter months of 1942, frozen and dried plasma derived from nearly 100,000 bleedings obtained by the Blood Donor Service was made available to the U. S. Public Health Service to be used by the Emergency Medical Service of the Office of Civilian Defense in the event of a civilian disaster caused by enemy action. Blood for such use is now collected under the auspices of the Emergency Medical Service of the Office of Civilian Defense through its grantee hospitals. However, in the event of a catastrophe, the chief of the local Emergency Medical Service may call on the technical supervisor of an American Red Cross Blood Donor center to provide whole blood as such or as a source of replacement for Office of Civilian Defense supplies of plasma that may have been utilized for a natural disaster rather than one caused by enemy action. This has been found to be a useful and practical supplementary function of the Blood Donor Service on several occasions.

About 6,000 units of dried plasma has also been released by the Surgeon General of the Army to the American Red Cross and is held by the Disaster Relief Service in various parts of the country. This constitutes a source of plasma to be used to meet the needs of the civilian population that may occur because of a catastrophe not related to the war.

SUMMARY

1. The American Red Cross Blood Donor Service, as the sole agency for the collection of blood to be processed into plasma and albumin for the armed forces,

20. The standard Army-Navy plasma package now being supplied contains twice the amount of plasma-citrate mixture that it formerly did, i. e. 600 cc.

procured 4,762,308²¹ pints of blood up to Nov. 1, 1943. At present donors are being accepted at the rate of 110,000 per week.

2. The Blood Donor Service, through its 35 centers and their 60 mobile units, offers to 45 per cent of the total population of this country the opportunity to donate blood.

3. The work of the Blood Donor Service is carried out by 129 doctors and 911 nurses, with the additional help of a large number of Red Cross volunteers.

4. The donor requirements and the method of procedure are rigidly standardized throughout the service.

5. The scope of this project has provided an opportunity for various studies and the investigations which have been outlined.

6. Because of the employment of full time experienced personnel and standardized methods of procedure, operational losses have been minimal.

ISCHEMIC MUSCLE NECROSIS

CRUSHING INJURY, TRAUMATIC EDEMA, THE CRUSH SYNDROME, TRAUMATIC ANURIA, COMPRESSION SYNDROME: A TYPE OF INJURY SEEN IN AIR RAID CASUALTIES FOLLOWING BURIAL BENEATH DÉBRIS

E. G. L. BYWATERS, M.B. LOND., M.R.C.P. LOND.
LONDON, ENGLAND

When in 1940 the air blitz on London started, we expected to see patients with "shock," a mysterious condition with as many definitions as there are writers on it, something that could be produced by natural processes such as burning, bleeding and bruising, as well as by such unnatural practices as injecting histamine, ground up muscle tissue and snake venom, and roentgen irradiation. The patients that we saw were suffering from the consequences of aerial bombardment. Most of them were only frightened—pale, rather cold, often described as "shocked." But the blood pressure was often rather above normal, and all they needed was rest and reassurance. Others we saw had severe lacerations; their pallor, coldness and sweating were accompanied by a low blood pressure and by a gradual hemodilution such as could be explained by the severe hemorrhage they had had. This surely was nothing mysterious but a reaction to blood loss, and when we remedied this by transfusion all went well. And then at last, rather later than the other casualties that had been admitted, some patients arrived who appeared to merit this label. With signs neither of external nor of internal hemorrhage these patients were pale, cold and sweating: the radial pulse was thready and weak, their blood pressure was low, and their blood showed hemoglobin concentrations of 140 and 160 per cent Haldane (19-22 Gm. of hemoglobin per hundred cubic centimeters). Was this not the same "shock" that had been seen in World War I when Cannon and his associates¹ described cases with hemoconcentration? Since then, although Moon² avers that hemoconcentra-

21. As of March 1, 1944 the total bleedings procured at the centers amount to approximately 6,400,000.

Contributed by request.

Dr. Bywaters is Beit Memorial Research Fellow.

From the Department of Medicine, British Postgraduate Medical School.

This paper, in a symposium on "War Injuries," is published under the auspices of the Section on Urology.

1. Cannon, W. B.: Traumatic Shock, New York and London, D. Appleton & Co., 1923.

2. Moon, V. H.: Shock, London, Henry Kimpton, 1942.

tion occurs in "shock," few other observers have found it except after severe burns, after intestinal injuries or in dehydration. Now all these patients gave a history of burial beneath debris for several hours, often with compression of a limb by fallen masonry: the affected limb was swollen—perhaps, we conjectured, because of plasma leakage. Whether this was so or not, it appeared that plasma had been lost from the blood stream, and so therefore we replaced it and with excellent results. The blood pressure rose, the hemoglobin level came down and the patient seemed on the highway to recovery. In the rush of work the first urines were often discarded without testing, but later what were thought to be red cells were seen, suggesting a genito-urinary injury; some of these patients developed oliguria and died in uremia with pathologic changes in the kidneys. With this lead, later cases were studied more carefully and a clinical entity emerged of which "shock" was only a facet. This was a specific response to a specific type of trauma: the clinical syndrome called "shock" is only a part of many diverse processes set in motion by various noxious agencies, conspicuous because common to all. The abstraction of certain common features from all types of trauma and the labeling of these as "shock," the conception of "shock" as a real entity with a cause and a mechanism, with as many books and papers written about it as were written about that other fabulous concept the unicorn in more ancient times, seemed to us to have done more harm than good. What was needed was a careful study of specific responses to trauma. This the Medical Research Council set out to do for "crushing injury." Cases of this nature were notified through the Emergency Medical Service by observers in all parts of the country, and the M. R. C. has now particulars, sometimes scanty, sometimes more detailed, of about 100 cases. While most of this material is as yet unpublished, protocols of the earlier cases may be seen by reference to the original publications.³ The following brief account has been compiled from material collected by the M. R. C. and its observers in Britain to familiarize readers in the United States with the salient features of the condition and with the present state of knowledge in this country regarding pathogenesis and treatment.

PREVIOUS LITERATURE

Despite the occasional occurrence of this type of injury in civil accidents apart from aerial bombardment, as after mining accidents (McClelland⁴), traffic acci-

dents (Bywaters, Belsey and others⁵), industrial accidents (Glen⁶) and mob stampedes (unpublished data), the condition seems heretofore unrecognized in English speaking countries. In Germany, however, the condition was recognized during World War I. Frankenthal⁷ in 1916 was the first to describe muscle necrosis in soldiers buried as a result of mine explosions, and reference is made to a probably similar injury recorded by von Colmers⁸ in 1910, in civilians buried during the Messina earthquake. This aspect is dealt with in the official Handbook of Military Surgery (Kayser⁹). Anatomic changes in the kidney were first mentioned by Hackradt in 1917 and Bredauer in 1920, whose findings are summarized, with those of other German authors, by Minami.¹⁰ It appears probable that, as we failed to recognize the condition in World War I because of the distance from the front line to the base hospital with its better equipped facilities for investigation, so we have failed to recognize the similar condition in traffic accident cases owing to the exclusive attention directed to the surgical aspects of these severe injuries. The only reference to these traffic accident cases that we have been able to find is the paper of Husfeldt and Bjering¹¹ from Oslo. In this war many air raid cases still pass unrecognized, particularly those with less severe degrees of damage, frequently diagnosed as "foot drop." However, publication of the air raid cases has stimulated the recognition of uremia following civilian accidents in this country, and it is to be expected that similar cases will be found in other automobile using countries. In large night raids on urban areas, crushing injury may account for about 5 per cent of all casualties.

CONDITION ON ADMISSION

Any patient admitted from a bombed area two hours or more after the incident must be questioned carefully as to whether he was buried or pinned down, and for how long: if there was compression for two to three hours or more, the patient will say that the limb was very painful for a short time and then went numb. On examination—and some patients are unable to give any adequate history—as soon as the grime and plaster are cleared away, patches of erythematous skin are seen delineating accurately the area of compression. The whole body must be examined: while in most cases the limbs are involved, in a few, areas of pressure on the trunk or neck have been responsible for symptoms. In fat people particularly the deep swelling which follows is very liable to be missed if the trunk is affected. The erythematous areas may progress to blister formation, which have several times been mistaken for burns. Soon after release from the compression the affected limb becomes swollen and hard: there is no subcutaneous, pitting edema, as the fluid is almost entirely beneath the deep fascia. The affected muscle is insensitive and paralyzed: superficial skin sensation is lost, usually over a rather patchy distribution, but sometimes corresponding to nerve trunk lesions. Later the tenseness passes off, palpation elicits a peculiar "doughy" sensation and pitting edema can appear.

OLIGEMIC HYPOTENSION

The general condition of the patient may at first give rise to no concern: the blood pressure is normal or slightly raised. Within a few hours, however, in patients with extensive lesions (one leg and thigh, or more), the damaged area swells and the blood volume is correspondingly reduced by plasma leakage through the damaged capillaries into the extravascular tissue spaces of the injured part. The patient becomes pale and cold; beads of sweat stand out on his forehead, and the pulse becomes thin. The blood pressure is maintained at its previous level by arteriolar vasoconstriction, until a moment arrives when this process can no longer compensate for the decreasing blood volume (due to continued plasma loss). At this juncture, which may be precipitated either by warming the patient under an electric bulb cradle or by anesthesia preliminary to operation, the blood pressure will fall to levels of 60-80 mm. systolic or lower, and the blood will be found maximally concentrated with a hemoglobin level of 140-160 per cent Haldane (19-22 Gm. per hundred cubic centimeters) and a raised plasma protein concentration. If the patient has bled, as from a scalp wound, this hemoconcentration will be masked by a parallel hemodilution and the net change may be very small (chart 1). Oligemia with hemoglobin 160 per cent Haldane corresponds to a plasma volume of 1 liter: it must be treated—and preferably before the hypotensive phase—by plasma or serum transfusion. Often more than the lost 2 liters may have to be used, as the injected fluid merely leaks out. Restraint of this continued local loss may prove to be a useful measure, as by the bandages suggested by Patey and Robertson¹² or by the plaster casts used by Trueta. There is some experimental evidence (Duncan and Blalock,¹³ Swingle¹⁴) that such measures will diminish the severity of "shock" in untreated dogs with legs crushed in a spring clamp and in other types of local shock-producing damage.¹⁵ Whether or not bandaging or plaster will decrease or increase the uptake of the hypothetical nephrotoxin from the damaged area in the animal is uncertain from the data so far published. In human cases a plaster, put on before maximal swelling, may later cause obliteration of the arterial pulse and have to be removed if further dam-

age is to be avoided.¹⁶ It seems probable that after some twenty-four hours plasma leakage is halted, perhaps by recovery of normal capillary permeability aided by increased tissue tension and reduction of extravascular osmotic pressure due to metabolites. The aim, therefore, of plasma transfusion is to maintain blood pressure at a normal level for the first day, and for this purpose a continuous infusion is necessary. If more than 2 liters is necessary, whole blood should be used, as the hemoglobin often tends to fall in these severe cases, leaving a residual anemia. The mechanism of this is as yet unknown: diapedesis and thrombosis in the damaged area would seem to play only a small part.

THE LOCAL CONDITION

In some cases as the swelling in the limb increased, either spontaneously or following intravenous fluid, the distal pulse decreased and the foot or hand became

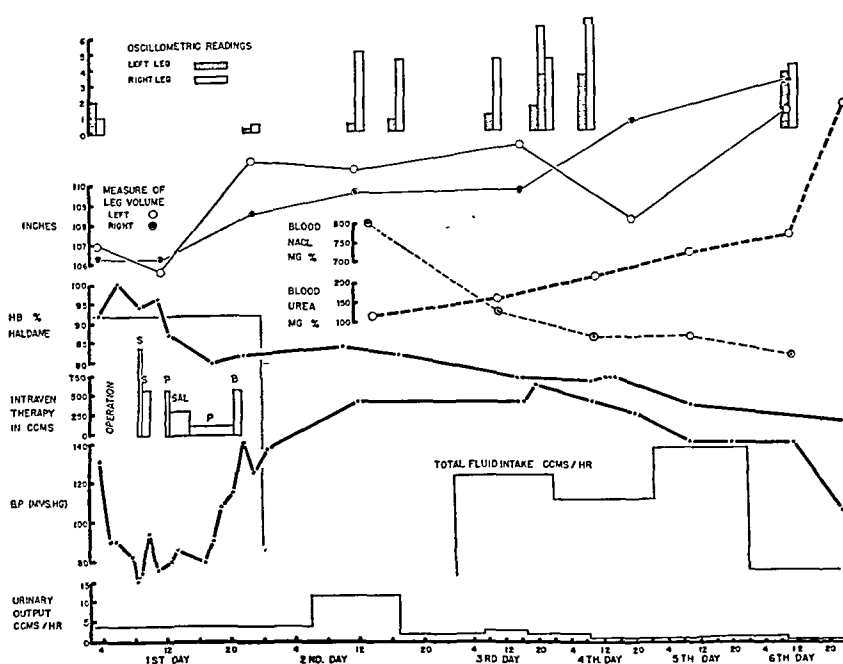

Chart 1.—Clinical course of a crushing injury case (Bywaters and Beall²⁷) buried six hours. Note from above down: 1. Return of circulation to legs as measured by oscillometer readings. 2. Increase in leg volume measured by spiral bandage. 3. Hemoconcentration and later hemodilution shown by hemoglobin level. 4. Blood pressure fall and restoration after transfusion. 5. Decreased urine output with rising blood urea. Urine contained pigment granules and casts and failed to concentrate urea above 670 mg. per hundred cubic centimeters. Necropsy showed blanching and necrosis of muscle in both legs and a typical swollen kidney.

pale and cold. Oscillometric readings confirmed the diagnosis of ischemia. In some cases the blood flow returned spontaneously and then the pulse was often greater than in the opposite uninjured member. In other cases the surgeon, thinking that perhaps the swelling of the muscle in the deep fascial compartment was compressing the artery, made an incision along the course of the artery: much serous fluid seeped from the wound and pale necrotic muscle bulged out. Obviously there had been a great increase of tension locally, which had perhaps obliterated the venous return. Following this procedure, in some cases a pulse was restored distally: in others the artery was found to be in spasm and periarterial stripping was thought necessary. It seems probable that arterial spasm alone without much increase of subfascial tension may sometimes be responsible for peripheral ischemia, particularly if hemorrhage into the adventitial sheath has occurred.

RENAL FUNCTION

The first urine passed after admission is usually highly acid (p_H as low as 4.6) and shows a brown sediment of acid hematin granules. These are frequently thought to be erythrocytes, a mistake that was made in our first cases. The supernatant urine may be normal in color, and the brown deposit is then sometimes overlooked by inexperienced staff. More usually, however, the supernatant urine is of a smoky color; only in urines with a p_H approaching neutrality is the urine red, and in such urine there is usually little or no sediment. Rarely the first urine obtained is normal: this is seen in very shocked patients and represents urine excreted into the bladder before the burial. With systolic pressures below 70-80 mm. of mercury, little urine is excreted. The pigment in the urine often shows a broad band in the red, signifying a met- compound, as well as two bands in the yellow-green portion closely resembling those of oxyhemoglobin. But, as will be detailed later, the pigment is not hemoglobin. It is always necessary to centrifuge such bloody, benzidine positive urine and to examine the deposit microscopically. If red cells be found, as may happen with rupture of a kidney, it is a mistake to assume that pigment in the supernatant is always derived therefrom. Lysis of such erythrocytes occurs usually only in infected urine. Hemoglobinuria, however, is said to occur with renal infarcts.¹⁷ Within one or two days the excretion of pigment ceases: casts become more numerous, at first consisting mainly of pigment granules, aggregated to form hollow tubes. Later the casts become rather stringy, and toward the end of the first week the pigment core is covered by a layer of desquamated epithelial cells. Sometimes these late casts appear to be entirely cellular. The amount of urine excreted decreases progressively in severe cases until the end of the first week, quantities such as 25-50 cc. in twenty-four hours being passed. Its composition tends to resemble glomerular filtrate in that the concentration of urea is low—often below 1 Gm. per hundred cubic centimeters with a blood level of over 300 mg. per hundred cubic centimeters—and the chloride content tends to be high despite a blood concentration below the normal level. Reducing substances are occasionally found in small amounts. Thus there is evidence of severe tubular dysfunction, although the total output is low rather than high. This we¹⁸ have thought to be due perhaps in some part to mechanical blockage of the tubules but mostly to leakage of filtrate back into the blood stream through damaged tubules. Other substances present in abnormal quantities in the urine are potassium and creatine. Both these substances are derived from damaged muscle, and both occur in largest quantity in the first specimens of urine passed after release.

GENERAL CONDITION

As a result of this excretory impairment, nitrogen retention occurs; the patient becomes rather drowsy, occasionally anxious and apprehensive. Vomiting may occur, another factor tending to reduce the blood chloride level. The serum carbon dioxide combining power may be low soon after release from compression, as

the result probably of the liberation of lactic and other acids from the damaged muscle, but rises thereafter: in cases with excretory impairment the carbon dioxide combining power may show a late tendency, to fall, as the result of retention of acid. Some patients have undergone laparotomy for abdominal pain without anything definite being found: sometimes pain in the loins is complained of, perhaps because of tension of the renal capsule. The blood pressure progressively rises to levels between 150 and 200 mm. of mercury and is maintained until death or the recovery diuresis ensues. It seems possible that this may be directly related to renal ischemia.

RECOVERY

About one third of the cases ordinarily recognized go on to recovery. These show on the average a smaller volume of necrotic muscle than the fatal cases—one lower leg or part of the lower thigh or one arm involved. The mildest type has no hypotensive phase, although some hemoconcentration can usually be found. The urinary output may remain good throughout, or it may be low for the first day with rapidly increasing volume and urea concentration thereafter: the blood urea level therefore rises only to a limited extent, to 60 or 100 mg. per hundred cubic centimeters on the second day, and then falls to normal. They are left with unimpaired renal function and some slight weakness in the affected muscle. A more severe type, which none the less ultimately goes on to recovery, is not infrequently seen: in these there is oliguria and severely decreased urinary urea concentration, with a blood urea as high as 400-500 mg. per hundred cubic centimeters. At the critical period on the sixth or seventh day a diuresis occurs and is maintained for several days until all the retained nitrogen is excreted. At the same time the raised blood pressure begins to fall to normal. Renal function, however, although it appears to recover completely, does so slowly: and the concentration of urinary urea will rise by about 50 mg. per hundred cubic centimeters daily in the third week. It may take five months for the urea clearance to reach normal figures.⁵ Damage to the compressed muscle is never completely repaired if complete ischemic necrosis has occurred. The infarct is replaced by fibrous tissue; calcification sometimes occurs, as in the only English case from the last war that I have been able to find, recorded recently by Albert and Mitchell.¹⁹ With lesser degrees of damage, regeneration of muscle fibers from the sarcolemmal sheath occurs and muscle strength gradually improves. Fibrosis may result in a Volkmann's contracture: it is important, therefore, to splint the limb correctly.

TERMINAL COURSE

Two thirds of the patients die toward the end of the first week, the majority on the sixth day. Death occurs very suddenly and may be preceded by cardiac irregularity. If electrocardiographic tracings are taken, changes similar to those seen in human potassium poisoning are seen—increased T waves and widened QRS complexes. These are associated with an increase of the potassium level in the serum to more than twice the normal upper level of 20 mg. per hundred cubic centimeters. The raised serum potassium concentration

in crushing injury is due to two processes: first, the muscle potassium diffuses out into the blood stream, its concentration falling from 300 to 70 mg. per hundred cubic centimeters or lower, both in man and in animals; secondly, very little of this is excreted owing to renal failure, and thus it accumulates in the body. The condition is analogous to the toxic condition induced by feeding potassium to dogs with ligated ureters,²⁰ except that the potassium is endogenous. If insulin and dextrose are given to a patient with raised blood potassium and similar electrocardiographic changes due to obstructive anuria, the blood potassium level will fall and the T waves decrease in height, owing to storage of potassium.²¹ This therapeutic lowering of potassium level may be found useful in cases in which there are indications of improving renal function, such as an increasing output and urea concentration (chart 2). It is important, therefore, that these patients should not be given meat or drugs containing potassium salts.

PATHOLOGIC CHANGE IN THE KIDNEYS

The pathologic changes in the kidneys of 22 patients have already been fully described (Bywaters and Dible¹⁸) and little new has emerged since then regarding structural damage. Briefly the kidneys resemble those of renal failure following intravascular hemolysis, being swollen and tense, with foci of tubular necrosis most pronounced in the boundary zone (distal convoluted tubule) and showing pigmented casts from the distal convoluted tubule downward. Many of these patients had had group O blood transfusions, but they showed no incompatibility, no rigor or post-transfusion backache, no jaundice or abnormal plasma bilirubin concentration (with the exception of a single case described by Longland and Murray²²) and neither hemoglobin-like pigment nor methemoglobin in their serum.

Some patients had had neither blood nor serum and yet they showed the full picture. We therefore dismissed the possibility of this being due to intravascular hemolysis and found on examining the urine more closely that the pigment differed from hemoglobin in several important respects.²³ Its α band had a wavelength of 5,810 angstroms as compared with hemoglobin at 5,780 angstroms; the CO-span, that is, the shift of the band on converting to carboxyhemoglobin, was only 30 angstroms instead of the 60 angstroms shown by hemoglobin. The pigment, in fact was myohemoglobin, the intracellular hem-compound responsible for oxygen storage in muscle. Its identification furnished us with a reason for the curious phenomenon of "hemoglobin" appearing in the urine without any being detectable in the blood plasma. Since it has a molecular weight of 16,700 compared with 68,000 for hemoglobin, it filters out through the glomerulus as rapidly as it is taken up from the muscles; it does not accumulate in the blood stream because by virtue of its low threshold, 20 mg. per hundred cubic centimeters (compare with 100 mg. per hundred cubic centimeters for hemoglobin),

its renal clearance is twenty-five times as great as that of hemoglobin.²⁴ Perhaps the best known condition in which this pigment is excreted is paralytic equine myohemoglobinuria: after a period of rest and rich feeding, sudden exercise of the horse produces acute stiffness, swelling and paralysis of muscles, with hemoconcentration, a thready pulse, acidosis and the passage of muscle pigment in the urine. In those animals that die, autopsy shows pale necrotic muscles resembling fish flesh, and an acute nephrosis.²⁵ Seven cases have occurred in man, and in what was thought to be the eighth case degenerative changes were seen in the muscles, and the kidneys were indistinguishable from those of the crush syndrome.²⁶

PATHOLOGIC CHANGES IN THE MUSCLES

The muscles that have been compressed are found at autopsy or operation to be swollen, sometimes pallid, sometimes mottled with hemorrhage. The fibers are friable and opaque. There is a sharp demarcation between living and dead muscle, corresponding with the areas of pressure necrosis in the skin. Histologi-

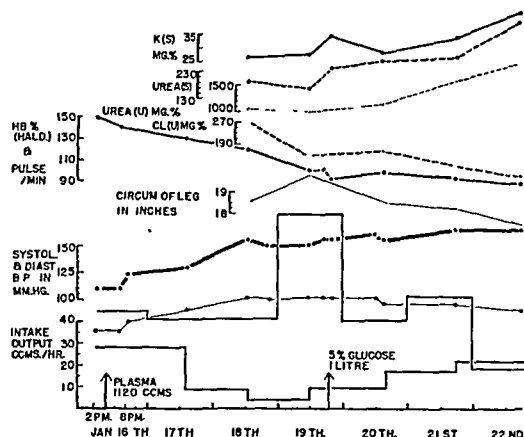

Chart 2—Course in a man aged 20 buried ten hours (Beall, Bywaters, Belsey and Miles²⁷). Note from above down: 1. Biochemical findings (rising serum potassium and urea, rising urinary urea and falling urinary chloride concentration). 2. Hemoconcentration and pulse. 3. Swelling of left leg. 4. Hypertension; no period of hypotension. 5. Intake well maintained. 6. Urinary output recovering. Death occurred on the seventh day with typical postmortem findings.

cally the fibers show loss of nuclei and retention of cross striation, with vacuolation and calcification in the boundary zone. Occasionally, however, cases apparently of crush syndrome are seen which show no gross alteration in muscle: in 1 instance (case 1, Bywaters and Beall²⁷) in which microscopic examination revealed occasional necrotic fibers in macroscopically normal muscle, we think this patchy necrosis was due to the ischemia of arterial spasm. During life the patient showed several features differentiating the case from the general run of "crush injury"—little hemoconcentration and yet a large decrease in blood pressure, two urine specimens free from protein, and a pulseless leg without progressive swelling. Autopsy revealed hemorrhage in the sheath of the popliteal artery, a lesion known to produce

violent spasm. In other cases the usual postmortem examination is not extensive enough to reveal muscle necrosis. The importance of finding myohemoglobinuria and creatinuria, therefore, is that these are indirect evidence of severe muscle damage; in all cases showing these substances in the urine a full muscle examination should be made. Cases do occur, however, in which the full crush syndrome picture develops and yet no prolonged pressure has occurred.⁵ These are patients, involved often in automobile accidents, with rupture of a main limb artery, with arterial spasm or thrombosis or with obstruction of the main artery by, for instance, a fractured pubic ramus. Each of these causes ischemia of muscle, which, if it lasts for more than several hours, produces muscle necrosis. This necrosis is hastened by the therapeutic warming which such cold pulseless limbs have so often suffered in the past. As soon as the collateral circulation returns to the part, the products of muscle autolysis are swept out into the general circulation and renal failure develops. It seems possible that this condition might occur with embolism of a main limb vessel or after a tourniquet has by mistake been left on for more than three hours, but I do not know of any such recorded cases. Another mechanism thought to account for the necrosis of complete muscles usually those deep set in a tight fascial compartment such as the posterior tibial, is that of obliteration of blood supply by increase of subfascial tension.²⁸

In summary, therefore, the essential lesion of crushing injury is muscle necrosis: this may be due to the ischemia of direct compression or it may be due to ischemia from interference with the main arterial supply by sudden spasm, thrombosis, rupture or obstruction.

PATHOGENESIS

In what way, then, does muscle necrosis produce renal damage? It is not due to the plasma leakage and low blood pressure alone because, in patients with prolonged shock due to lacerations and hemorrhage with a blood pressure below 90 for many hours, we have found no renal damage beyond sometimes a few casts and a temporary trace of albumin. Furthermore, Eggleton and her collaborators²⁹ have shown in the anesthetized dog that, following the "shock" period after histamine injection, no decrease in creatinine clearance is seen. The chief role in the genesis of renal failure in crush syndrome must therefore be played by substances absorbed from the damaged part.

We have recently analyzed such necrotic muscle from crushing injury; compared with undamaged muscle from the same corpse, it has lost 75 per cent of its pigment, 75 per cent of its phosphorus, 66 per cent of its potassium, 70 per cent of its creatine and 95 per cent of its acid producing substances (glycogen and so on). As has already been detailed, all these substances appear in the first day's urine in increased quantity. Rabbit muscle compressed by rubber tubing for a similar length of time loses all these substances except myohemoglobin within two or three hours after release;³⁰ that is, as soon as the circulation to the part is reestablished: histologically the muscle shows exactly the same

changes as those seen in man. At the same time all the changes characteristic of crush syndrome in man appear (hemoconcentration, hypotension, swollen limb, acidemia and oliguria with acid urine containing creatine) except myohemoglobinuria and renal failure. The rabbit's muscles contain no myohemoglobin: no myohemoglobin was excreted: no renal failure developed. We thought, therefore, that this pigment, of all the substances known to be lost from damaged muscle, ought to be investigated first, not only because of the rather negative results of compressing the rabbit's leg referred to,³¹ but because both the clinical course and the pathologic changes in man resembled so closely the results of a mismatched transfusion. The ill effect on the kidney of the latter was thought by Baker and Dodds³² to be due to the precipitation, in acid urine with high salt concentration, of acid hematin, and subsequent blockage of the tubules: rabbits with alkaline urine could tolerate hemoglobin injections indefinitely. We therefore made good this deficiency of rabbit muscle by injecting human myohemoglobin in quantities per kilogram of body weight comparable with those released in man; in animals with acid urine of a p_H equal to that seen in human beings we were able to produce death after four days in renal failure: the histologic changes in the tense swollen kidney were not, however, exactly similar to those seen in man. While mechanical blockage of the tubules may play a small part, it seems probable from some preliminary experiments that myohemoglobin in these rabbits with acid urine acts in a more direct way on the tubules, perhaps by producing a physiologic (resorption) blockage with a rapid rise in intrarenal pressure. It is far from certain, however, that this lesion is the same as that seen in man. In the anesthetized dog, whose muscles contain myohemoglobin, Eggleton, Richardson, Schild and Winton²⁹ are of the opinion that the depression in creatinine clearance which follows tight binding of the limb for five hours with additional crushing and hammering is not in any way due to blockage. Their experimental procedure produced flaccid kidneys, whereas, if blockage or tubular poisoning was involved, tense swollen kidneys should be found. They noted also that this depressed creatinine clearance could not be prevented by preliminary bicarbonate infusion. They conclude that disturbance of no single mechanism could account for all the observed phenomena. A further interesting observation has recently been made by Eggleton,³³ using the anesthetized cat. Employing a technic similar to that we used in the rabbit, she found that following release of the compression the creatinine clearance fell 50 per cent, while if the circulation was readmitted slowly to such ischemic limbs there was no change. Later experiments suggest that the liver, given time, was able to detoxicate the blood returning from the damaged area. Again, it is not yet certain that this renal damage produced in cats and dogs is the same as in man, since in the latter the criteria are clinical, whereas in these acute animal experiments no data on recovery have yet been obtained: the criterion has been chiefly that of creatinine clearance.

DIFFERENTIAL DIAGNOSIS

It must be remembered that injuries may often be multiple: "blast lung," "fat embolism" and cardiac infarction are complications we have seen which confuse the issue. We have recently seen hemoglobin concentration of 19.8 Gm. per hundred cubic centimeters in a man buried for twenty-four hours resulting from paralytic ileus from pressure of a truss pad, without any gross muscle necrosis. Oliguria due to mismatched blood transfusion, oligemic hypotension and crystal calculi must be differentiated. Hematuria and hemoglobin may be differentiated by examination of the urine.

TREATMENT

Treatment is to be considered under four headings:

1. *Administration of Fluid and Alkali.*—The first and most urgent step is an attempt to guard against renal failure by the establishment of an alkaline diuresis. Instructions should be issued to civil defense personnel to give sodium bicarbonate by mouth and nonmilky fluids such as tea, coffee and water if possible before release from compression of patients buried for one to two hours or more: if necessary, release should be delayed for twenty to thirty minutes to allow this to be done. Patients so treated should wear an identifying label and be followed with especial care. It seems probable, however, that most patients will not have had this alkali and fluid given before they enter the hospital. They should be given sodium bicarbonate or other mild alkali 4 Gm. hourly by mouth until the urine is alkaline. Dosage should then be continued over the next two days, to maintain alkalinity, at a rate of about 30 Gm. a day. Should vomiting preclude oral administration or if it is desired to alkalize the urine within two hours, 1 liter of isotonic sodium lactate (one-sixth molar = 2 Gm. per hundred cubic centimeters) should be given intravenously. This may be made up in small bottles of 50 cc. in tenfold strength (20 Gm. per hundred cubic centimeters) and diluted ten times before use. (It keeps well and can be sterilized by boiling or autoclaving.) If this is not available, 3 to 4 per cent sodium citrate may be given but has the disadvantage in large amounts of producing tetany. Sodium bicarbonate (1.4 per cent) may also be given intravenously, but, as this will decompose on heating in the open, sterilization is difficult: in an emergency a measured amount may be dissolved in sterile water (2 teaspoons to a pint) and injected without sterilization. It must be emphasized that this alkalization to be effective should be early and thorough, being controlled by the reaction of the urine. If possible it should precede measures taken to improve the circulation in the injured part. A fluid intake of at least 3 liters daily should be assured, either by mouth or by vein. The volume of the urine must be measured over twenty-four hours.

2. *Treatment of "Shock."*—This should follow hydration and alkalization. The patient may be leaking plasma into the injured area, sometimes without outward sign if the trunk is affected. This may pass on to "oligemic shock," although the blood pressure remains normal for a time because of vasoconstriction. Since renal function is likely to be further impaired by a fall in blood pressure, it is important that this "preshock" stage should be recognized and prompt

treatment instituted. Serum or plasma should be given before the blood pressure falls—in the stage of hemoconcentration. Blood may be necessary if more than 2 liters of fluid has to be used or if hemorrhage has occurred. Morphine should be given for pain. The patient should not be heated, unless he is uncomfortably cold, and then blankets will probably be sufficient.

3. *Local Treatment.*—The injured limb should be kept cool with ice bags, as this will decrease the rate of autolysis and also allow living tissue to survive on a low margin of blood supply.³⁴ Immobilization may prove a useful measure, since absorption of large mole-culed substances occurs chiefly by way of the lymphatics. If circulatory obstruction should occur, fascia splitting incisions may be made along the course of the main limb vessels, once the urine is alkaline. Plaster casts may be applied after splitting the fascia but not before (unless they are bivalved): a closed cast may prove a more dangerous constricting agent than a tight fascial sheath. If obstruction is due to spasm, this may be relieved by stripping or resection of the damaged portion of the vessel.³⁵ Amputation should be done only if the leg is so severely damaged as to be useless and then in the first twenty-four hours. The value of tight bandaging is uncertain: while it will decrease the severity of shock by limiting fluid loss (Duncan and Blalock,³⁶ Katz¹⁵) observations have yet to be made of its effect both on the kidneys and on the residual local lesions. Later, splinting will be necessary in the optimal position; physical therapy and occupational therapy will have an important part to play in the recovery of function.

4. *The Treatment of Cases with Established Renal Failure.*—If renal damage is well established, all therapeutic efforts may be unavailing. On the other hand, some patients with very severe lesions and high blood urea levels (e. g. up to 490 mg. per hundred cubic centimeters) have recovered without any treatment other than bed rest. The results of any particular treatment must therefore be viewed with a critical eye. The use of diuretics such as sodium bicarbonate and concentrated serum may be of value. Mercurial diuretics have also been used, and decapsulation has been advocated. Insulin and dextrose may prove to be of value in some cases.

In conclusion, very little is yet known about the effects of therapy. The evaluation of treatment depends on the ability to forecast the outcome without treatment, and that is often difficult, even with the complete investigation possible in research centers. Further work is needed, both from the experimental laboratory and, using suggestions derived therefrom, in man. For this, that very full collaboration between physician, surgeon and pathologist is needed which, on a larger scale, between freedom loving nations, is beginning to emerge as one of the few happy developments of these unhappy times.

INJURIES TO THE KIDNEY

A. J. SCHOLL, M.D.

LOS ANGELES

Injuries to the kidney vary from mild contusions to complete maceration of the entire renal mass. The majority occur in men, owing not only to greater exposure and more strenuous physical activity but also to the more inflexible muscular fixation of the kidney.

Injuries to the kidney are divided into open, or penetrating, and closed, or nonpenetrating, wounds. During peacetime the majority of renal injuries are of the closed type, occurring in civilians and resulting from traffic and industrial accidents and not infrequently from vigorous athletic activity, particularly football. Usually these injuries are slight, causing some pain and hematuria and requiring only expectant treat-

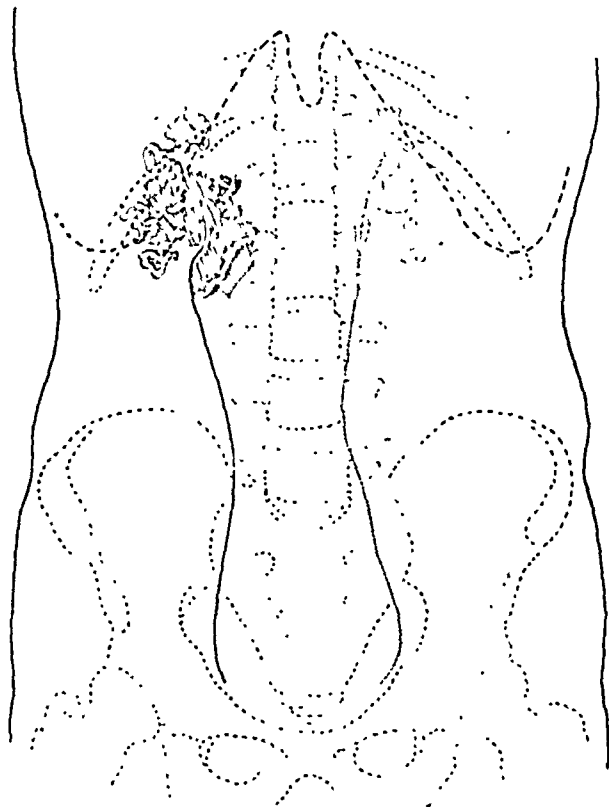

Fig. 1. Extensive tear of the renal pelvis following efforts to extract a stone impacted at the ureteropelvic junction.

ment. In wartime the incidence of penetrating wounds increases, and these are mainly gunshot injuries, due either to rifle bullets or to shrapnel. Apparently the location and protective covering of the kidneys prevent them from being injured by other types of war wounds, such as air and immersion blast injuries. In blast injuries, usually the lungs and hollow viscera alone are affected, the kidneys and other solid organs rarely being damaged.

Recent advances in urologic diagnosis, use of the newer urinary antiseptics and more conservative surgical procedures have all reduced the seriousness of both types of renal injuries and the incidence of both early and late complications and sequelae.

PATHOLOGY

Closed injuries to the kidney vary from a slight subcapsular hemorrhage to complete destruction of the parenchyma with or without injury to the hilus. The

most common lesion is a tear through the capsule with mild injury to the parenchyma, usually causing only moderate pain and hematuria and rarely necessitating surgical treatment. Patients requiring surgical intervention generally have rather extensive damage with multiple fissures of the parenchyma which may at times completely fragment the kidney. The blood vessels are always torn, bleeding is free and perirenal hematomas are common. On surgical exploration, the most striking feature is the large amount of clotted and free blood surrounding the renal mass. If the capsule is not torn, the bleeding may cause only a localized subcapsular hemorrhage. In some cases one pole, or both, is torn from the kidney, or the kidney may be divided by a deep fissure which opens directly into the pelvis. Extensive parenchymal tears usually follow a transverse line of cleavage which opens up between the large tubules and vessels. If the fissure involves only the parenchyma, rarely will urine be found in the wound, but if it extends into the pelvis or calices, extravasation of urine usually occurs. If the injury is slight and the urinary extravasation small, the urine may be absorbed or it may form a perinephric abscess with extensive adhesions and matting of the perirenal tissues. In patients without infection and with intact perirenal tissues, pseudohydronephrosis may result.

Rupture of the renal pelvis occurs occasionally during instrumental urologic manipulations, most commonly during efforts to manipulate calculi either in the pelvis or in the upper part of the ureter. Occasionally very extensive tears of the pelvis may result from vigorous attempts to deliver a rigid instrument with its attached stone. In 1 case, at surgical exploration of the kidney several days after such an accident, two fingers could readily be passed into the renal pelvis (fig. 1). In such injuries to the pelvis and ureter, urinary extravasation spreads rapidly, and unless early exploration is carried out, infection, edema and adhesions make any conservative procedure impossible.

Perforation of the renal pelvis or renal parenchyma may result from the use of stiff or styleted ureteral catheters. Fortunately such accidents, which possibly are not always recognized, rarely cause permanent damage.

Nontraumatic, or spontaneous, rupture of the kidney is extremely rare. In most reported cases it has occurred in diseased kidneys. Infection, chronic nephritis and hydronephrosis are the most frequently associated conditions. Henline¹ was able to collect only 24 cases from the literature and reported 1 case of his own of a spontaneous rupture resulting in a perinephric abscess which burrowed down to the perineum. In some cases the trauma is so slight as to be overlooked or not considered a factor in the rupture of the kidney.

Penetrating injuries, whether caused by gunshot or stab wounds, rarely affect only the kidney; usually the renal injury is of minor importance, being not infrequently overlooked. The most common penetrating wounds of the renal parenchyma are of the perforating type, although furrows, complete destruction of either pole or extensive shattering of the kidney may occur. In penetrating injuries, as with closed lesions, parenchymal wounds may be slight, especially those in which the edges or poles are damaged. When the center of the kidney is injured, the damage is usually severe.

This paper, in a symposium on "War Injuries," is published under the auspices of the Section on Urology.

1. Henline, Roy Biggs: Spontaneous Rupture of the Kidney, J. A. M. A. 83:1411-1414 (Nov. 1) 1924.

The nature of the projectile has little particular effect on the injury, although bullet wounds destroy a portion of parenchyma only slightly larger than the size of the bullet, whereas shrapnel makes a more irregular wound, with greater destruction of tissue. In shrapnel injuries the edges of the wound are more likely to be contused, and the adjacent parenchyma may become necrotic on account of arterial injury.

In wounds involving the hilus, the renal artery or one of its larger branches may be divided. When the renal artery has been severed the patient usually dies before reaching the hospital; when one of the larger branches has been cut through or obstructed by formation of a clot, nephrectomy is usually resorted to. Although renal veins anastomose, the arteries do not, and consequently arterial injury, even of the smaller vessels, may cause extensive cortical necrosis. In an occasional case the renal vessels are divided, leaving an intact ureter. The renal pelvis and the renal artery and veins are infrequently injured, though they may be injured by the same missile.

SYMPTOMS AND DIAGNOSIS

Hematuria, pain and abdominal rigidity are present in most cases. The location of the wound and the presence of hematuria are usually the first indications of renal damage in penetrating wounds.

Pain and Abdominal Rigidity.—In slight injuries only tenderness may be present, but in the majority of cases pain is present, varying in degree from a constant discomfort to severe and agonizing colic, which usually increases on movement. Like renal colic from any cause, the pain may radiate to the groin or into the thigh. Pain is due to injury to the soft parts, distention of the renal capsule or passage of blood clots down the ureter. Rupture or tear of the renal pelvis, particularly in cases of instrumental injury, causes a sudden, sharp onset of severe pain. There are partial fixation and rigidity of the abdominal wall and tenderness on abdominal palpation over the injured kidney and in the corresponding costovertebral region. Rarely is abdominal relaxation sufficient to permit accurate palpation of the renal region, although in some cases extensive perirenal bleeding produces a large mass in the flank which is readily felt through the rigid muscular wall. When the abdomen has been perforated by a bullet wound, extensive abdominal rigidity is usually present, although either partial or generalized abdominal rigidity does not always mean a lesion of the peritoneal cavity. Gunshot wounds of the chest or chest wall, extensive hematoma of the renal region or intra-abdominal hemorrhage from any condition also can cause abdominal rigidity.

Shock.—Usually, though not always, shock is present. In uncomplicated cases it is generally not severe and depends to a certain extent on the amount of blood lost. Fear, exposure and delay greatly increase the incidence of shock in war injuries. Shock developing after several days usually means either increased or recurrent bleeding. In cases in which an injury to the abdominal viscera, thorax or spinal column is associated, shock usually is severe. Even in uncomplicated renal injuries, however, the severity of shock is not always an accurate index of the degree of renal damage.

Hemorrhage.—Bleeding is the most serious complication, usually involving the kidney and perirenal tis-

sues. In some cases the bleeding is extensive, forming a massive perirenal hematuria. The bleeding has a tendency to cease spontaneously, possibly owing to increased pressure in the restricted perirenal space. An associated rupture of the peritoneum permits the blood and urine to drain from the closed lumbar space into the peritoneal cavity; occasionally large amounts of blood and clots must be removed from the peritoneal cavity at the time of renal repair.

Hematuria.—Varying from microscopic amounts to massive hemorrhage, blood is present in the urine in most cases, although the hematuria may not occur immediately. In the early stages it is not excessive, and after several days it tends to cease spontaneously. If the wound involves only the parenchyma of the kidney, hematuria may be slight or absent.

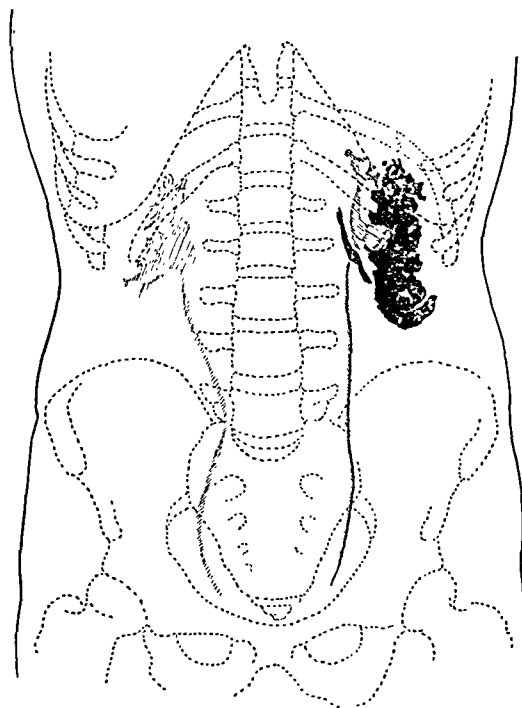

Fig. 2.—Complete pulpification of the kidney associated with rupture of the spleen and tear of the peritoneum.

It is necessary to make certain that the blood is coming from the kidney and not from the bladder, as the blood coming from the latter is a not infrequent manifestation of associated injury of the spinal cord, particularly in cases of gunshot injury. In all cases of wounds of the flank, the urine should be examined for microscopic evidence of blood. If necessary, catheterization should be done, as retention is common in cases of renal injury and may be due to a concomitant lesion of the spinal cord. Absence of hematuria may be due to division of the ureter, to obstruction of it by clots or fragments of renal tissue or to extensive damage to the renal pelvis.

Secondary hemorrhage into the bladder is fairly frequent and is most common in the second or third week after injury but may appear as late as two months afterward. It is not unusual for late hemorrhages to be so severe that they cause death. Consequently it is desirable, even in cases in which only slight renal injury is present, to keep the patient absolutely quiet,

preferably at rest in bed, for at least two weeks after injury. Secondary hemorrhage may be spontaneous or it may be an exacerbation of persistent primary hemorrhage. Differing from the primary bleeding, it may be accompanied by clotting of blood in the bladder.

Urography.—Roentgenographic examination gives definite diagnostic information relative to the state of the kidney and the possibility of associated bony lesions and should be made as soon as the patient reaches the hospital, as gas distention develops quickly and obscures the renal outline. A plain roentgenogram of the kidney may be taken in the presence of extensive secondary injuries which prohibit more detailed urologic studies. Haziness of the renal outline, obliteration of the margin of the psoas muscle or deviation of the spine away from the injury suggests perirenal bleeding (fig. 2).

Excretory Urography.—In the case of war injuries there rarely is time or opportunity for excretory uro-

They have the disadvantage that the secretory powers of the kidney may be inhibited or reduced by trauma and that in the presence of shock the ability of the kidney to secrete is reduced still further by a drop in blood pressure and lowered volume of blood to the kidney. During the period of recovery the secretory power of the damaged kidney as well as that of the sound, contralateral organ is inferior to the immediate post-traumatic ability to secrete. Domrich³ has shown that the secretion of the kidney continues after trauma as long as the tissue and renal blood supply are intact but that during recovery secretion of a traumatized and intact kidney is less than that observed immediately after trauma. Therefore in most cases excretory urography performed shortly after rupture gives the most reliable information concerning the gravity of the lesion. There are cases, however, in which early excretory ureteropyelograms are unsatisfactory and in which better results may be obtained twenty-four to forty-eight hours later.

Excretory urography is particularly graphic in cases of minor injury to the kidney and is usually of more diagnostic assistance in cases of gunshot wounds than in cases of rupture from civilian trauma, as gunshot wounds frequently leave a large proportion of the kidney undamaged. In some instances of even fairly extensive tears, sufficient opaque solution is secreted by the remaining normal segment of parenchyma to indicate the extent of damage present.

Prather⁴ states that lack of visualization of the injured kidney in an intravenous urogram is important and indicates the presence of a pathologic process requiring surgical exploration. By contrast, visualization of the injured organ does not rule out injury. Stirling and Lands⁵ were able to make a positive diagnosis by means of an intravenous urogram in 23 of 34 cases studied. A retrograde pyelogram was necessary in only 7 of their cases.

Cystoscopy, Ureteral Catheterization and Retrograde Pyelography.—Sometimes these may be necessary to establish the diagnosis, and usually they give much more accurate information than that obtained by excretory urograms. However, in the case of war injuries lack of time or equipment usually prohibits these procedures in the early days after injury. Moreover, cystoscopy is usually hazardous in the presence of shock or extensive bony lesions. Exacerbation or recurrence of bleeding may follow shifting of the patient's position or, more rarely, instrumental manipulations. When cystoscopy is indicated and can be carried out, and time and the condition of the patient permit, it should be done.

Retrograde pyelography offers definite, accurate information concerning the condition of both the injured and the opposite kidney (fig. 4). The risk of infection resulting from cystoscopy is slight, and no harm comes from injecting the newer, absorbable contrast solutions. On the other hand, cystoscopy is rarely necessary in cases with slight trauma and minimal bleeding.

In the majority of cases of gunshot wounds, particularly those encountered in the front line hospitals, the

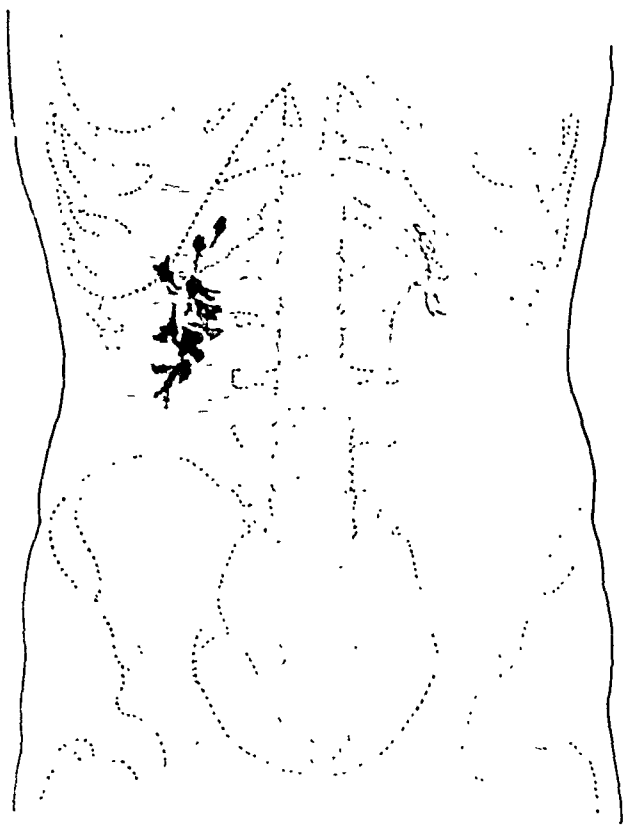

Fig. 3.—Intravenous urogram, showing multiple extensive tears of the parenchyma of the right kidney.

raphy in the first few days after trauma, but when possible it is of great assistance. Intravenous urography aids in locating and defining the extent of the injury and determines the presence and function of the opposite kidney. While the incidence of single kidneys is low, the possibility should be considered in all cases. Turton and Williamson² reported 1 case of traumatic rupture of a single kidney and collected 4 more from the literature; the right kidney was absent in all the cases. If a fair concentration of the opaque medium is excreted by the injured kidney, it is probable that the renal injury is slight and early treatment unnecessary.

Excretory urograms, similar to plain roentgenograms, can be made in the presence of extensive complications and even when the patient is unconscious (fig. 3).

finer points of diagnosis obtainable by cystoscopy are time consuming and unnecessary. The only immediate questions to be settled are Is operative intervention imperative? and Is the opposite kidney capable of sustaining life in the event that nephrectomy is obligatory? The intravenous urogram usually gives a satisfactory answer to both of these questions. With penetrating injuries the physical findings, site of entrance of the projectile, pain, swelling and hematuria generally determine the diagnosis and the location of the lesion. With closed wounds the history of trauma and persistent pain and hematuria suggest the need for further investigation.

In those cases in which satisfactory ureteropyelograms are obtained, the visualized changes in the course of the ureter and the outline of the renal pelvis give accurate information concerning the pathologic changes

other a severe urinary infection which was still present one year later. Three patients with minor renal injury, as reported by O'Connor,⁶ resumed their active life a short time after injury, and all 3 later had massive hemorrhage which required surgical intervention.

The main point to be settled regarding any renal injury, penetrating or nonpenetrating, is whether exploration is necessary and, if so, when. Some surgeons state that patients having a history of trauma and hematuria of more than twenty-four hours' duration should have exploration. Others favor a policy of watchful waiting. Lowsley and Menning⁷ declared that any patient who has a history of trauma and who has had hematuria for more than twenty-four hours should have the benefit of an exploratory operation. They state that such a procedure is now considered to be more conservative than hopeful waiting. When there are

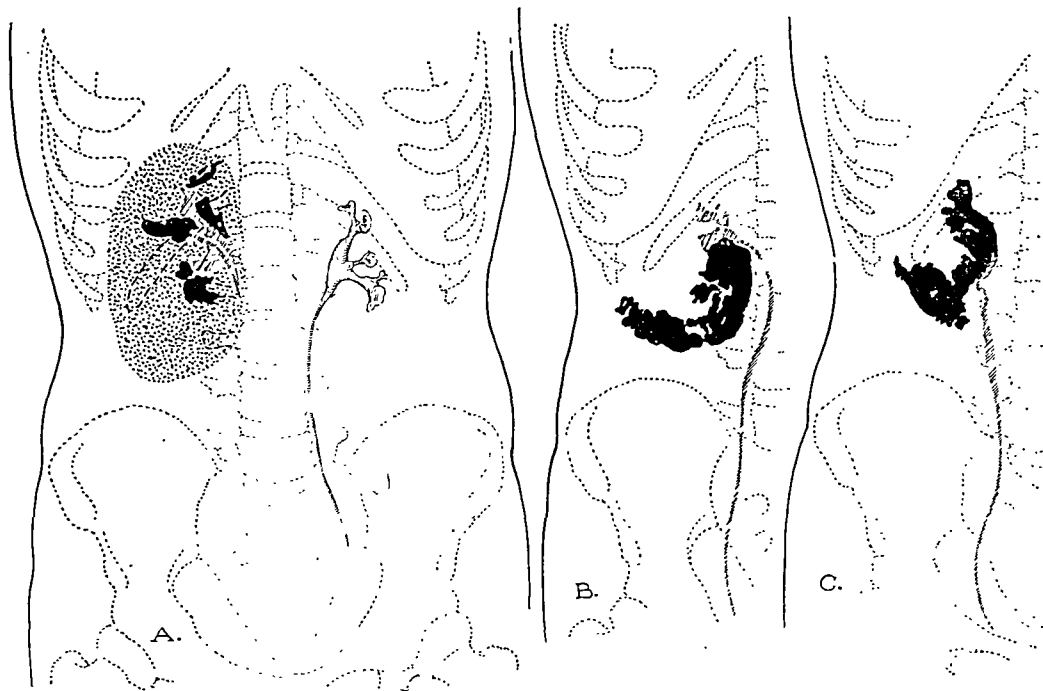

Fig. 4.—Rupture of the right kidney. *A* shows a large hematoma extending from the costal margin to the crest of the ilium. *B*, taken two weeks later, shows the palpable mass to be much smaller, with extension of the shadowgraphic substance around the lower pole of the kidney. *C*, a pyelogram taken two months after injury, showing the renal mass to be approximately normal in size. (Case of Dr. C. F. Rusche.)

present. Deviation of the ureteral outline toward the vertebral column, upward displacement of the ureteropelvic juncture and narrowing of the calices suggest perirenal extravasation.

TREATMENT

In many cases, particularly of penetrating injuries, care of the renal condition is less urgent than that of complicating lesions, and in a large number only conservative local treatment is necessary. Palliative treatment is sufficient and yields good results in the majority of both open and closed types of injuries, but bed rest is essential, and careful observations should be made of the extent of hematuria, of the amount of pain and for evidence of hemorrhage and infection. Early return to routine life may cause serious trouble. Two of my patients, football players with mild renal injury, returned to active life after only a few days rest; one had an extensive secondary hemorrhage, the

signs of internal hemorrhage, such as a rising pulse rate and a falling blood pressure, immediate operation may be necessary, but in the average case little is lost by a period of observant waiting. This delay allows the patient time to recover from shock; the necessary diagnostic examinations may be carried out and, if exploration is finally necessary, surgical hemorrhage is usually less in amount than it would have been immediately after injury. The final decision as to whether to explore the renal area depends on the surgeon, and it varies in individual cases. Continuous hematuria and signs of infection or of internal hemorrhage all indicate that extensive damage is present and that exploration is necessary. Sometimes, even though

7. Lowsley, O. S., and Menning, J. H.: Treatment of Rupture of the Kidney, *J. Urol.* 45: 253-271 (March) 1941.

the patient has recovered from the immediate effects of the injury, some surgical procedure may be necessary to prevent later complications or even complete destruction of the kidney.

Shock, common with war wounds, is rare with uncomplicated renal injuries and should be treated symptomatically. When it is due to renal bleeding, exploration of the kidney is indicated. Hematuria, even though pronounced, is not sufficient reason for early surgical exploration. Primary hematuria usually subsides in twenty-four to forty-eight hours, but if it persists and is profuse the kidney should be explored. Urinary extravasation usually calls for early and extensive incision and free drainage of the region.

In cases of a penetrative wound or a closed wound with extensive trauma in which it is doubtful whether the abdomen or the renal region should be opened, one should remember that lumbar incision carries less risk, and that, if necessary, the abdomen can be explored through the same incision. The renal region should be explored first. An adequate lumbar approach permits evacuation of clots and thorough visualization of the kidney and opens an easily drained region that may be securely packed if necessary. After repair of the kidney is completed the lower angle of the incision may be elongated transversely, the peritoneum opened in front of the colon and the adjacent viscera examined. This is especially important in gunshot wounds, as the peritoneum and its contents are damaged in more than 90 per cent of the cases.

Abdominal Approach.—In cases in which primary abdominal exploration is performed and renal damage is probable, the kidneys should be palpated. In some cases positive information is obtained by use of this route, but, if injury is present, usually an obscured field due to perirenal bleeding makes it difficult to determine the extent of renal damage even if the posterior layer of peritoneum has been opened over the kidney. Exploration of the renal region transabdominally is usually not advisable, as it opens up a poorly drained field, which is readily contaminated from frequently present abdominal infections. If during abdominal exploration a hematoma or obvious renal damage is found, it is unwise to open the posterior portion of the peritoneum for either further exploration or evacuation of clots. For the same reason transabdominal nephrectomy is particularly hazardous, bears a high mortality record and should rarely be done. Many fairly large perirenal hematomas do not need immediate evacuation. Although they may eventually cause further renal damage and disability, no harm results from delaying their removal until opportunity and the state of the patient make this procedure safe.

When conditions found during the course of laparotomy indicate that exploration of the renal fossa is necessary, a second incision should be made, with the lumbar approach. It is, however, preferable to postpone renewed intervention for several days. On the other hand, early exploration is imperative in cases in which bleeding from the kidney is excessive, although it may have incited considerable shock.

Wounds of Kidney, Liver and Diaphragm Combined.—Combined wounds of the kidney and liver, although serious, usually require only conservative management, and frequently surgical intervention is neither advisable

nor necessary. Wounds of the diaphragm encountered in the course of exploration of the kidney rarely require repair.

Surgical Procedures for Wounds of Kidney.—In the treatment of wounds of the kidney there are three possible surgical procedures: (1) drainage of the renal region, (2) partial nephrectomy and repair of the injured kidney and (3) nephrectomy.

Drainage of Renal Region: This is the most satisfactory procedure in cases of penetrating wounds, especially when shock is present and exploration urgent. It permits inspection, evacuation of blood clots and control of bleeding. It is the simplest procedure and may be done quickly with only slight risk to the patient. Foreign bodies and fragments of shrapnel should be searched for carefully and removed. All loose fragments of tissue should be taken out. Drainage should be free and plentiful. The drains should be placed carefully to reach all parts of the wound. In closing the incision one should take care not to suture so tightly that obstruction of drainage results.

Drainage is indicated if time or the condition of the patient has not permitted complete studies to determine the condition of the opposite kidney.

If hemorrhage is encountered, an effort should be made to control it with catgut ties or sutures. In suturing or clamping bleeding points one should exercise care not to injure the peritoneal contents or the great vessels; on the right side the duodenum lies close to the kidney and is easily damaged. No large segments of tissue should be grasped with toothed forceps, and no extensive or deep suturing should be done without certain knowledge of the involved structures. Usually general oozing does not permit complete localized hemostasis and is best controlled by packing with iodoform or plain gauze. Lumbar incision permits firm packing, and sufficient gauze should be used to control all bleeding. A piece of rubber dam or similar material should be spread in the wound before packing to facilitate removal of the gauze and to prevent recurrence of bleeding when the gauze is taken out. When lacerations of the kidney are severe and when the patient is in a precarious condition, thorough packing controls the hemorrhage until the patient is better able to stand nephrectomy.

When the kidney is not removed and drainage is installed, it should be continued until at least the tenth postoperative day.

Partial Nephrectomy, Renal Repair and Plastic Operations: These procedures frequently are employed with satisfactory results for closed, uninfected, civilian types of renal rupture but usually are unsatisfactory for infected, penetrative wounds. Many injuries for which a plastic operation would be sufficient and satisfactory will heal without surgical intervention. Extensive plastic procedures following widespread destruction of the kidney not uncommonly result in a functionless kidney. When partial nephrectomy or suture has been done, parenchymal infection, necrosis and late bleeding may necessitate reopening the wound later and, in some cases, secondary nephrectomy.

The control of hemorrhage usually calls for surgical intervention. A partial nephrectomy is not likely to remove the cause of the bleeding, and a patient already anemic should not be exposed to the risk of a fresh hemorrhage from a sutured or a partly resected organ.

Rarely are limited operations justifiable in the treatment of penetrative wounds.

Nephrectomy: The kidney should be removed in cases of persistent hematuria, multiple deep lacerations of the parenchyma or damage to the vascular pedicle. A patient who has rupture involving the entire vascular pedicle rarely reaches the operating table in a condition suitable for operation.

When the ureter is severed, the pelvis torn or the kidney lacerated and urine is escaping from the wound, results are usually poor unless nephrectomy is done. However, in the presence of a ureteropelvic tear, slight or no infection and a sound kidney, no harm results from the flow of urine over tissues as long as it has a free exit.

Nephrectomy is a simpler procedure than most conservative or repair operations and usually removes the cause of bleeding. In the small group of cases in which the condition of the patient is satisfactory and the kidney so damaged that ultimate nephrectomy will be necessary, or there is uncontrollable bleeding from the kidney, nephrectomy is the procedure of choice. Nephrectomy takes less time than a repair, removes a potential field for infection and limits future bleeding from the operative site. It also eliminates a secondary operation and the late disability and sequelae which so frequently follow reparative procedures.

In the early days after injury nephrectomy is difficult and hazardous. Most observers agree that in only rare instances is early nephrectomy indicated or advisable. Increased experience has shown that in many cases, particularly of gunshot wounds, in which early nephrectomy would formerly have been employed, better results are obtained by efficient drainage; nephrectomy, if it is necessary, is left until a later date.

LATE RESULTS

Patients who have nephrectomy for an injured kidney usually obtain good results and are able to lead a normal life. On the other hand, complications are frequent in patients treated medically and by conservative surgical measures. Pyelonephritis, urinary fistula, hydronephrosis, ureteral stricture and stone formation not uncommonly occur. Infection is common in untreated patients, at times persisting for years. Perinephric abscess, which occasionally develops, may be drained, leaving the kidney intact.

Dózsa⁸ reported 83 cases of injury to the kidney. Conservative treatment was satisfactory in 79 and operation was performed in 3. Twenty-seven of the patients were seen from six months to thirty years after the initial injury and had to be operated on for probable consequences of the renal injury. Hydronephrosis was present in 6, renal stone in 9 and tuberculosis of the kidney in 10. Priestley and Pilcher⁹ reported a series of 45 cases of ruptured kidneys, 31 of which they were able to follow for periods ranging from four to twenty-six years after injury. Eleven patients who underwent nephrectomy were entirely free of symptoms, 73.7 per cent of those treated medically were entirely well and the remainder of the group had mild symptoms referable to the urinary tract. Cheeth-

am¹⁰ reported a series of 25 cases of so-called late complications seen at various periods after renal injury. All gave a definite history of renal trauma. Three of the 25 were treated medically, but some type of operation was necessary for the remaining 22.

Colston and Baker¹¹ presented a series of 13 cases in which definite pathologic changes in the kidney or perirenal tissue had occurred at varying periods after renal injury. While not condemning conservative treatment of renal injuries, these authors stated that the surgeon must be familiar with the changes that may follow injury and take steps to prevent their development. They said that some of the serious effects might have been prevented by better and earlier surgical methods.

MORTALITY

Collected statistics on renal operations, most of which were published shortly after the turn of the century, suggested that the mortality following renal trauma, whatever the treatment, was high. These statistics were usually based on small groups of cases in which treatment had been carried out in the formative days of renal surgery. Many of the injuries were not recognized early, some milder injuries were overlooked and operation when performed was carried out during a period when any surgical approach to the kidney was attended by a high mortality. These early statistical reports, still quoted by recent textbooks on renal operations, are not comparable to those obtainable with modern accurate diagnostic measures, skilful parenchyma conserving plastic procedures and efficient, universally employed, urinary antiseptics. There was no mortality in a series of 43 cases reported by Cheetham,¹⁰ in 31 of which operation was performed, and there were only 2 deaths, both attributed to severe extrarenal trauma, in a series of 45 cases reported by Priestley and Pilcher.⁹

On the other hand, the mortality is high in complicated cases. Hinman¹² stated that injury of the kidney complicating extensive involvement of certain internal organs becomes a part of the general abdominal problem. Twenty-seven of Hinman's group of 137 cases of renal injury were of this type, and all 27 patients died shortly after admission to the hospital.

Statistical reports from different countries vary widely with regard to the incidence and mortality of war injuries, but agreement is general concerning the rarity of uncomplicated renal lesions and the high mortality in complicated cases. Laewen¹³ collected and reported a group of 57 cases of gunshot wounds through the abdomen and kidney treated in German hospitals; there were only 5 cures, giving a mortality of 87.7 per cent. The results of treatment in British war hospitals are more encouraging. The reports of Wallace,¹⁴ Lockwood and his co-workers,¹⁵ Fraser and

Drummond¹⁶ and Walters and his associates,¹⁷ published in 1917 and later reviewed by Young for the Surgeon General's report, covered a series of 2,121 cases of gunshot wounds of the abdomen. The kidney was involved in 155 (7.3 per cent) of these cases; 57 per cent of the patients died. For 69 uncomplicated wounds of the kidney the mortality was only 14 per cent. In the American Expeditionary Forces the kidney was involved in 129 of 2,385 cases (5.44 per cent) of gunshot wound of the abdomen. The mortality rate in this group, for both complicated and uncomplicated cases, was 55.8 per cent.

SUMMARY

Renal injuries, both penetrating and nonpenetrating in type, are of infrequent occurrence. Most injuries are mild, causing only slight pain, hematuria and moderate abdominal rigidity. Many penetrative renal injuries require no treatment, and exploration of the renal region should be done only when there is extensive, persistent or recurrent hematuria and free perirenal bleeding, or extensive renal damage is suspected. Early recognition of the renal damage, conservative surgical treatment and suitable bed rest have definitely reduced the mortality and complications of both the penetrative and the nonpenetrative type of injury.

The location of the wound and the presence of hematuria are usually the first indications of renal damage in penetrating wounds. Roentgenographic examination gives valuable information relative to the state of the kidney and the possibility of associated lesions. Excretory urography is of value in indicating the location of the lesion and determining the presence and function of the opposite kidney. If cystoscopy is indicated, and time and the condition of the patient permit, it should be done.

The main points to be settled regarding the treatment of renal injury are whether exploration is necessary and, if so, when. When there are signs of internal hemorrhage, immediate operation may be necessary, but little is lost by a period of observant waiting. This allows time for the necessary diagnostic procedures to be carried out and time for the patient to recover from immediate shock, and, if exploration is finally necessary, surgical hemorrhage is usually less in amount than immediately after injury.

The three most common surgical procedures for both penetrating and nonpenetrating wounds are drainage, nephrectomy and plastic repair. Drainage of the renal area is the most satisfactory early procedure, especially in cases of penetrating wounds. It is simple and brief and permits evacuation of clots, removal of fragments of tissue and foreign bodies and the packing of the region to control hemorrhage. Nephrectomy is employed only when removal of the kidney is urgent, as when there is persistent excessive hematuria, extensive destruction of the vascular pedicle or complete shattering of the kidney. Plastic repair of the kidney, which is not infrequently carried out with success in closed civilian types of injury, is rarely indicated in the penetrative wounds. It is time consuming, at times it is followed by infection and hemorrhage and in some cases nephrectomy is necessary later.

INJURIES OF THE URETER AND THEIR MANAGEMENT

ROBERT B. McIVER, M.D.
JACKSONVILLE, FLA.

Wounds of the ureter alone are rarely encountered, either in civil or in military practice. In a survey of the collected cases of wounds of the urogenital tract from the records of the American Expeditionary Forces (World War I) Young¹ found only 4 cases of injury to the ureter alone. A survey of the records from our clinic revealed 25 cases of ureteral injury, in each of which it was unilateral. The etiologic classification of the series is given in table 1.

TABLE 1.—Etiologic Classification

25	♂	R	Direct trauma	Vesical anastomosis.....	Recovery

The management of these injuries depends on the cause of the injury and on the time that has elapsed since it was sustained. If during a surgical operation the ureter is injured, immediate repair is indicated. The ends of a completely divided ureter may be united over a T tube or over a ureteral catheter passed upward to the renal pelvis and downward into the bladder. The anastomosis should be free of tension and the sutures, few in number, should not include the mucosa

From the Departments of Urology, St. Vincents and Duval County Hospitals.
This paper, in a symposium on "War Injuries," is published under the auspices of the Section on Urology.

and should be lightly tied. A patch of fat over the suture line assists in making a water-tight joint. Drainage to the point of anastomosis should be provided, preferably extraperitoneal. These points are well illustrated by the following case, in which operation was performed by an excellent general surgeon,² who consulted me at the time and who has kindly permitted the use of the following data:

CASE 18—A white woman aged 38, married, a quadripara, was undergoing a pelvic operation and the division of dense adhesions when the left ureter was unintentionally included in double clamps and divided. The accident was immediately recognized. A number 8 F. ureteral catheter was passed up the proximal ureteral segment to the kidney and down the distal segment to the bladder. End to end anastomosis was performed with use of number 00 chromic catgut interrupted sutures which avoided the mucosa. A tag of omentum was placed over the suture line. The catheter was removed after one week. The patient recovered without fistula.

Fig 1 (case 3)—Gunshot wound of right ureter: extravasation, opaque medium at injury

The importance of drainage cannot be overemphasized; this may be extraperitoneal, by preference, or transperitoneal, by necessity. Failure to provide for the drainage of urine, which usually leaks from the repaired injury, often results in serious complications and sometimes in the death of the patient. This is illustrated by the following case

CASE 21—During an operation for the removal of a large intraligamentary cyst of the ovary by a general surgeon the ureter was not recognized until after it had been severed, as it had been displaced by the tumor. The severed ends were brought together over a ureteral catheter passed upward to the renal pelvis and downward into the bladder. The anastomosis was tightly performed, but drainage to the point of anastomosis was not instituted. Several days later the patient became acutely ill and showed evidences of general peritonitis, despite the fact that the catheter had been draining regularly. Death ensued shortly thereafter, and the postmortem examination revealed general peritonitis resulting from urinary extravasation.

PENETRATING WOUNDS

Gunshot and stab wounds require immediate operation, particularly when they involve the peritoneal cavity.

Fig 2 (case 3)—End result in gunshot wound of right ureter.

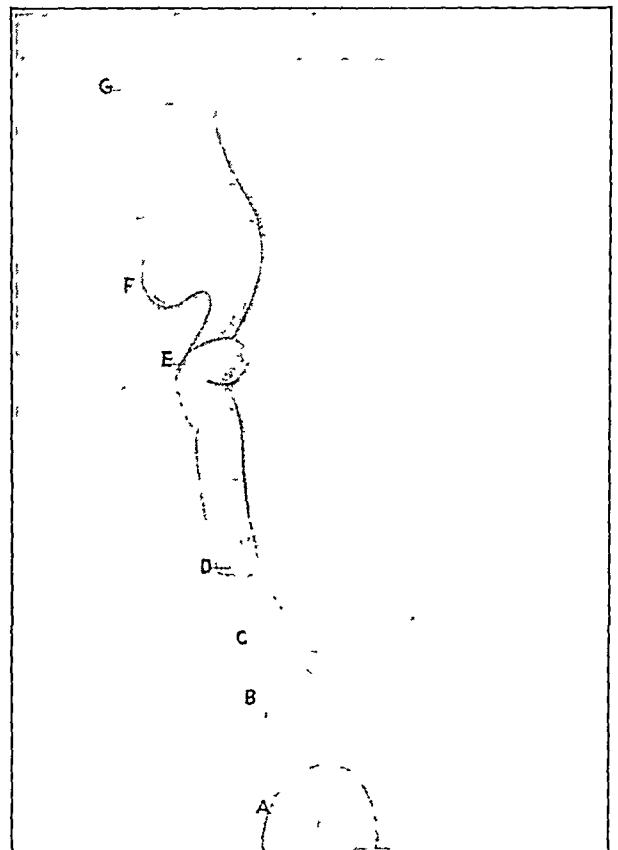

Fig 3—Condition revealed by vaginoureterovaginal graft: A, vulva; B, lower right ureter; C, fistulous tract; D, ureter above injury; E, additional ureteral obstruction; F, hydronephrosis; G, calcified glass

2 Harkness, R. B. Personal communication to the author, 1940

CASE 3.—This case is unique in that a bullet which entered the right lower quadrant of the abdomen traversed the pelvic peritoneal cavity, severed (incompletely) the right ureter, perforated the left side of the sacrum (lead marks) and was palpable under the skin of the left buttock; it injured several

SURGICAL WOUNDS

Accidental injury of the ureter not recognized at the time of operation usually results in complications, the more common of which are fistula, peritonitis and renal infection. In case of noninfected wounds, simple hydronephrosis followed by atrophy of the kidney may not give rise to acute illness and may not require surgical intervention. In the other group, urinary fistula develops in from one to three weeks, twelve days being the average in the series here reported. The fistula may communicate with the incision (skin) or with one of the nearby body outlets. Of the 9 cases, in 5 it complicated hysterectomy; in 2, removal of a large intraligamentous (retroperitoneal) ovarian cyst, and, in 2, excision of the rectum and rectosigmoid. The

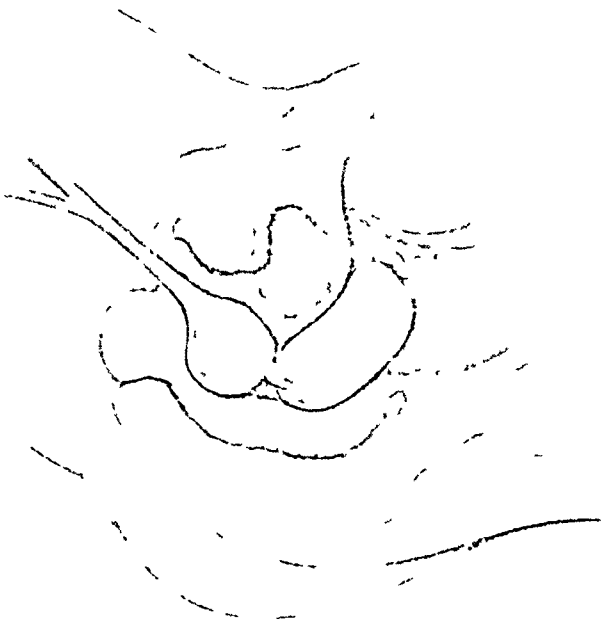

Fig. 4—Employment of bay catheter to introduce opaque medium.

loops of bowel but did not perforate the mucous membrane of any loop. The extravasated urine was drained transperitoneally, as the exploration had been done through a low abdominal incision. It was possible to pass a number 8 F.

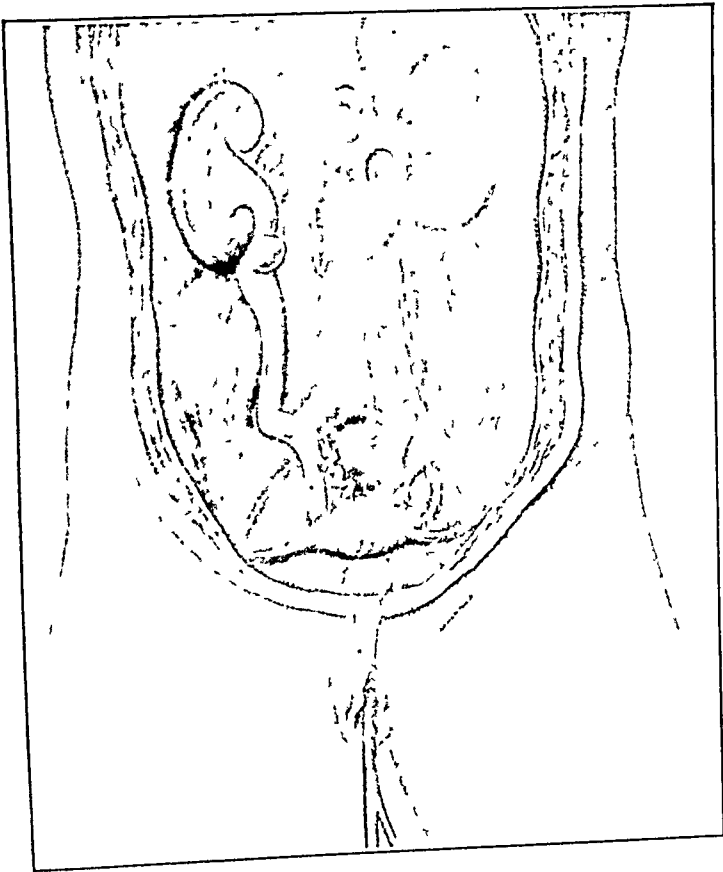

Fig. 5—Anterior view of dissection

ureteral catheter cystoscopically all the way to the renal pelvis, and the catheter was left in place for ten days. The recovery of the patient was uncomplicated except for an incisional hernia, which was repaired six months later (figs 1 and 2).

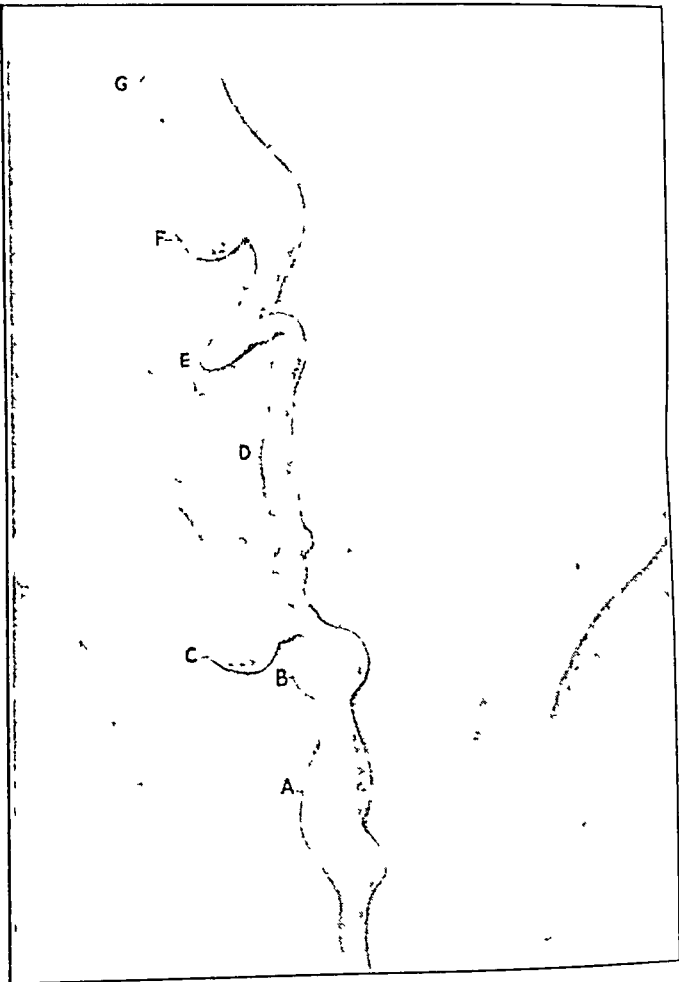

Fig. 6—Condition revealed by rectal space ureteropyelogram A, rectal space, B C, fistulous tract; D, ureter above injury, E, tortuous ureter, F-G, hydronephrosis

fistula communicated with the incision in 3 cases, with the vagina in 4 and with the rectal space in 2. Intravenous urography was helpful in demonstrating the side affected and in locating the site of the injury. Cystoscopy and ureteral catheterization in combination with x-ray and retrograde pyelography are the chief diagnostic procedures. Nephrostomy, pyelostomy or ureterostomy are necessary emergency measures in cases of obstruction or infection. The simplest and quickest drainage should be established for patients acutely ill. This temporary drainage may be sufficient in cases of ureteral ligation or incomplete trauma, as catheterization from below may be possible when the ureteral lumen becomes partially reestablished.

In exceptional cases the introduction of an opaque medium by way of the vagina (vaginoureteropyelography), the rectal space (rectoureteropyelography) or

the fistulous tract (fistuloureteropyelography) may aid materially in evaluating the case. These studies are made after the acute infection has subsided and are carried out in the following manner:

A 30 cc. bag catheter of the Foley type is introduced into the vagina, rectal space or other fistulous tract, as the case may be. The bag is inflated to block the outlet of the tract, and with the patient in the Trendelenburg position an opaque medium is injected through the catheter by means of a pressure syringe, and the roentgenogram is immediately made (fig. 3).

CASE 7.—A segment of the right ureter was accidentally excised during a hysterectomy. Primary anastomosis over a ureteral catheter was unsuccessful and resulted in a uretero-vaginal fistula. The vaginoureteropyelogram demonstrates (A) the vagina, (C) a fistulous tract, (E) an additional ureteral obstruction, (F) hydronephrosis and (G) a calcified gland (proved by other studies). Right nephrectomy was performed, and the patient recovered.

CASE 6 (fig. 4).—An injury to the left ureter, inflicted during excision of the rectum and rectosigmoid but unrecognized during the operation, resulted in a ureterorectal space fistula. The rectal space ureteropyelogram demonstrates (A) the rectal

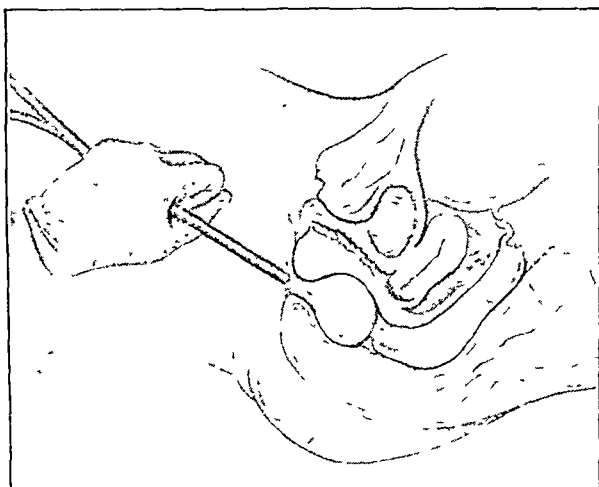

Fig. 7.—Use of bag catheter to introduce opaque medium

space, (B-C) the fistulous area and (F) the hydronephrosis above a tortuous ureter. Left nephrectomy was followed by recovery.

Intentional surgical wounds of the ureter are made for removal of an impacted calculus, for relief of obstructions, for removal of a growth and for various plastic procedures. Owing to a variety of causes, the fistula thus established may persist. Even after nephrectomy a persistent discharge may sometimes annoy both the patient and the surgeon. Ureterograms and fistulagrams, together and separately, will aid in establishing the diagnosis. Patient 11 came under our observation after five operations for calculi in the right kidney and ureter.

CASE 11.—A nephrectomy had been performed for calculous pyonephrosis, after which the patient had a fistula which drained profusely. Figure 9 shows (1) the fistulagram, (2) the right ureteral catheter entering the fistula and (3) the ureter above the fistula before the nephrectomy. Figure 10 shows (1) the ureterogram after nephrectomy, (2) the opaque medium outside the ureter, (3) the drainage tube in the fistula, (4) the pocket in front of the ileum, (5) the ureteral fistula and (6) the ureter. The wound failed to heal, and at a final operation, undertaken with the idea of ureterectomy, a foreign body (sponge) was found in the pocket in front of the ileum. After the removal of this foreign body the wound healed.

MANIPULATION OF URETERAL CALCULUS

Rupture of the ureter, with urinary extravasation, cellulitis and abscess formation, was observed in 6 cases of this series, and in each the rupture had fol-

Fig. 8—Further illustration of employment of bag catheter

lowed the use of instruments within the ureter. One patient died of sepsis from retroperitoneal abscesses. All intraureteral manipulations and instrumentations should be carried out with gentleness, and the surgeon should be prepared for immediate open operation if

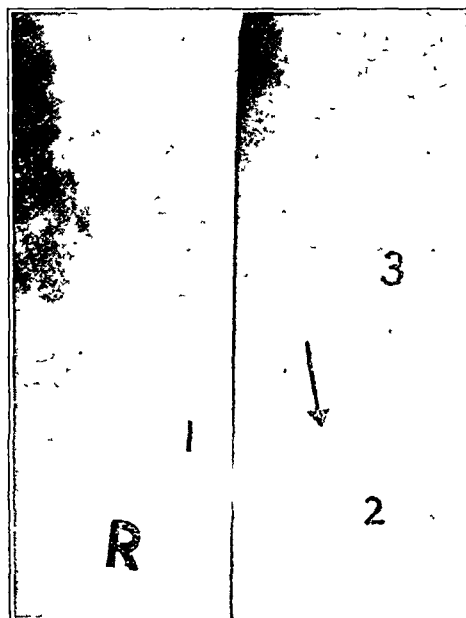

Fig. 9—1, fistulagram; 2, ureteral catheter entering fistula, 3, ureterogram

instruments other than ureteral catheters are to be employed. It is much safer to pass one or more ureteral catheters above an obstructing calculus and allow them to remain in place than to pass a wire basket or other instrument that might injure the ure-

teral mucosa or the entire thickness of the tube. If a basket is used and, after engaging the stone, the operator finds it difficult to extract the instrument, it should be left in place for twenty-four to forty-eight hours, during which time gentle traction is made at intervals.

The ureter which has been injured during the manipulation of a calculus should be catheterized immediately and the catheter left in place. If this is impossible and extravasation has occurred, immediate operation might reestablish the lumen, preferably over a T tube, one end of the T reaching into the bladder, the other up the ureter and the stem emerging through the incision. If this procedure is not possible, then one must either reimplant the ureter into the bladder, transplant the ureter into the bowel, transplant the ureter to the skin or perform a nephrectomy.

URETEROINTESTINAL ANASTOMOSIS

In cases of ureteral injury at or above the true pelvic inlet, reimplantation into the bladder is impossible. Anastomosis of the upper ureteral segment with the colon should receive consideration, particularly when (a) there is previous disease or damage to the contralateral kidney, (b) the kidney under consideration shows a good function, (c) the patient understands the operation and (d) the lesion is on the left side. In cases of injury to the lower urinary tract, I have performed transplantation of the ureter into the colon ten times (8 patients), with no deaths.

INJECTION OF CAUSTIC AGENTS

The accidental injection of a caustic fluid was formerly more likely when sodium hydroxide was included in the cystoscopic setup. This solution was easily mistaken for the opaque medium, and, when it was

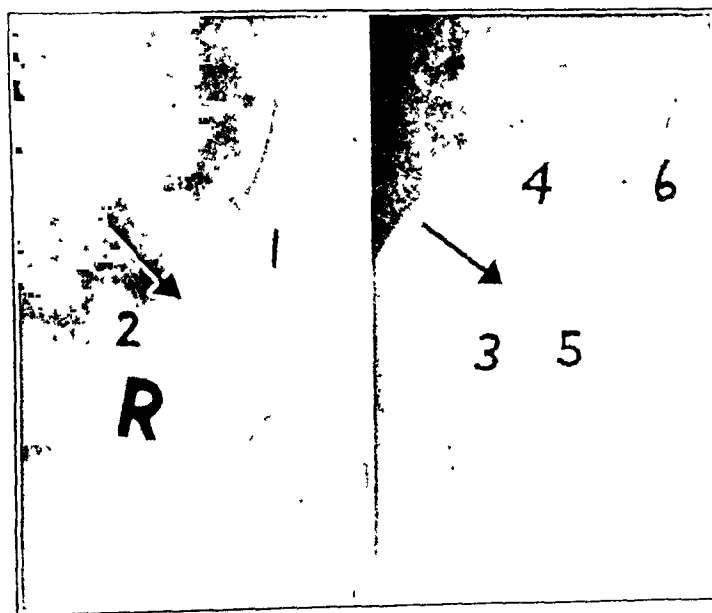

Fig. 10.—1, ureterogram; 2, extraureteral opaque medium; 3, tube in fistula; 4, pocket anterior to ilium; 5, ureteral fistula; 6, ureter.

injected into the ureter and renal pelvis, severe damage to both organs resulted. Two such cases came under my care in a previous decade:

CASE 1.—An elderly white woman was undergoing cystoscopic study. Labels on two bottles had been reversed, and sodium hydroxide was injected through the right ureteral catheter. The patient suffered excruciating pain and went into shock. Several days later a right nephrostomy was performed; the patient's condition was critical and became steadily worse. She died five days after the accident. The postmortem examination revealed suppurative pyelonephritis with cortical abscess and septicemia.

CASE 2.—During cystoscopic examination of a 40 year old white woman, sodium hydroxide was accidentally substituted for the opaque medium and injected through the left ureteral catheter. The patient immediately complained of exquisite pain and went into shock. The solution was withdrawn and the pelvis lavaged with water followed by diluted hydrochloric acid. The patient was returned to her room. The left ureter was drained by catheter. After several weeks of illness she made a partial recovery, at which time she came under our observation. The diagnosis was pyelonephritis, suppurative, chronic, left. Left nephrectomy was performed, and the patient recovered.

SUMMARY

1. Penetrating wounds of the ureter alone are seldom encountered in either civil or military practice.
2. Injury of the ureter should be treated surgically, promptly and with provision for adequate drainage.
3. Ureterostomy, pyelostomy and nephrostomy are employed to combat infection and obstruction.
4. Ureterointestinal anastomosis offers an opportunity to save the kidney in selected cases.
5. Nephrectomy is often necessary.

BLADDER INJURIES

INCLUDING SPINAL CORD INJURIES AS RELATED TO WAR AND CIVIL PRACTICE

ARBOR D. MUNGER, M.D.

LINCOLN, NEB.

This paper is suggested by reason of the present crisis through which the world is passing and concerns itself with injuries to the urinary bladder encountered as the result of warfare. Apart from consulting the records of personal experiences in a British base hospital and established medical department statistics from World War I, full acknowledgment is accorded the British surgeons Gordon-Taylor,¹ Clifford Morson² and Ralph Thompson,³ from whose publications material on the present war is largely based.

In the present world conflict, as in World War I, a definite ratio of bladder to general systemic injuries is occurring. The theme, however, in the present war differs in that the ratio is greater and, because of the predominance of high explosive bombing, the non-penetrating or concussion injuries considerably exceed the penetrating. During World War I it is estimated that about 70 per cent of bladder injuries were of a penetrating nature, whereas the blast injuries were at a minimum.

The concussion "blast" produced by modern aerial or artillery bombardments may rupture the abdominal viscera without external wound and produce extensive blood or urinary extravasation. Such injuries may result from hurling against the parietes fragments of wood, iron or masonry from demolished buildings.

The distended bladder has a decidedly increased liability to rupture in circumstances of trauma to the lower abdomen, and unless there is an associated fracture of the pelvis the empty bladder is very rarely ruptured.

This paper, in a symposium on "War Injuries," is published under the auspices of the Section on Urology.

1. Gordon-Taylor, Gordon: War Injuries of the Kidney, Ureter and Urinary Bladder, Post-Grad. M. J. 16: 125 (April) 1940.
2. Morson, Clifford: The Care of the Bladder in Injuries of the Nervous System, Practitioner 14: 305 (May) 1932.
3. Thompson, A. Ralph: Injuries of the Bladder, Brit. J. Urol. 12: 177 (Sept.) 1940.

Fractures of the pubis and the combined fracture of iliac and pubic portions of the pelvic girdle are the types of fractures which are especially prone to be complications with a ruptured bladder. In this respect the greater number of bladder injuries occurring in the present war do not vary manifestly in character from those occurring in our civil life as the result of automobile accidents, industrial injuries, and the like.

In a series of bladder injuries at an English base during World War I, 40 per cent of the bladder injuries were complicated by damage to the pelvic girdle; the pubic portion of the pelvic girdle was most frequently damaged, but no segment of its bony circumference was immune.

The severity of the osseous injury varies from simple perforation or mere notching to that of fragmentation with spicules of bone being driven into the cavity of the bladder. Bony rarefaction may occur with subsequent development of osteomyelitis and sequestration. Bony damage augments the risk and severity of bladder sepsis, with resultant formation of sinus tracts with prolonged discharge of urine and pus from the wound made by the missile or from the openings on the skin of the groin, perineum or thigh as the result of the diffusion of the infection.

Cuthbert Wallace, a British surgeon of World War I, in a series of 965 laparotomies performed at a British casualty clearing station found bladder injuries 45 times, or in 4 per cent of the cases. From a British base hospital during the last great war a detailed study of 53 cases of bladder injury revealed that 70 per cent of the wounds of gunshot origin had the point of entry in the buttock, 70 per cent had the missile retained and in 70 per cent there was concomitant injury of intestine, of bone or of both. The rectum was damaged in 19 cases, in 3 of which the wound was intraperitoneal and in 16 extraperitoneal. A suprapubic wound of entry was rarely encountered in gunshot wounds of the bladder. Rather, as just noted, the entry was mainly through the buttock with the missile traversing in an oblique and upward direction. Other wounds of entry less frequently encountered than the buttock were found in Scarpa's triangle, lower down the thigh and in the iliac fossa, groin, sacral and perineal regions. Bullet wounds of the bladder are occasionally through and through, and, should the empty bladder be perforated from side to side the lesion may assume a benign character.

Because of the awareness that bladder injuries are usually complicated, the time held concept of intraperitoneal and extraperitoneal damage as a simple lesion *per se* is revised.

The Manual of Military Urology incorporates the following statements:

Experience of this war has gone far to eliminate the classic distinction of injuries to the bladder whereby they are divided into two groups, the intra- and extraperitoneal. In the description of symptoms and treatment, however, the distinction of extra- and intraperitoneal injuries must be maintained for the sake of clarity. But in the field the surgeon will find that most of the intraperitoneal bladder wounds are associated with extraperitoneal wounds and that the diagnosis of extraperitoneal injuries founded upon the absence of abdominal tenderness and rigidity may ultimately be belied by a fatal peritonitis. The following classification, therefore, simply represents the various combinations which may occur and artificially dissociates the complex pathologic conditions resulting from wounds of the pelvis or abdomen that involve the urinary bladder.

1. Intraperitoneal injuries.

(a) Wounds.

1. Uncomplicated.
2. Complicated by
 - (a) Perforations of other viscera.
 1. The small intestine.
 2. The colon.
 - (b) Fractures or injuries of bones.
 - (c) Injury to large blood vessels.

(b) Ruptures by concussion.

1. Complicated.
2. Uncomplicated.

2. Extraperitoneal injuries.

(a) Wounds.

1. Uncomplicated.
2. Complicated by
 - (a) Injury to rectum.
 - (b) Injury to deep urethra or prostate.
 - (c) Fractures of the bony pelvis or femur.
 - (d) Injury to important blood vessels.

The symptoms of intraperitoneal wounds of the bladder vary according to the course and size of the lesion, the most noticeable being the urgent desire to urinate and usually the inability to do so. Frequently only a small amount of bloody urine can be expelled. Blood in the bladder is always present but frequently cannot be ascertained except by catheterization. Catheterization may reveal fecal material and gas formation in the bladder, denoting communicating injury of the rectum. With a catheter in situ, an anterior and lateral x-ray examination with air injection or the instillation of a dilute nonirritating opaque medium such as diodrast will establish a diagnosis.

The prognosis of bladder injuries accompanied by intestinal wounds during the first world war was dismal in the extreme. Mortality averaged better than 90 per cent.

It is suggested by Gordon-Taylor that the greatly increased mortality in cases in which operation is performed for intestinal and bladder injury over that attending the surgical treatment of intestinal injury alone may be related to the greater expenditure of time in securing good bladder suture at the end of a time consuming intestinal operation.

To the credit of ever improving surgical technics, the prognosis in bladder injuries with plurivisceral damage is no longer "dismal in the extreme." In the early hours after wounding, the surgeon's activities are now directed toward the immediate saving of life by recovery from shock, systemic antisepsis and adequate drainage, succeeding all of which the surgeon can institute deliberate reparative surgery.

Perforation of the small intestine is most common, but the large intestine and rectum are injured with great frequency. In urgent traumatic surgery of the abdomen no operation is complete until the bladder has been thoroughly inspected. Frequently an unsuspected gunshot wound of the bladder is discovered during the laparotomy. The bladder should be sutured whenever the condition of the patient and the accessibility of the vesical wound render this possible. Intraperitoneal wounds present no difficulty unless the rent is situated at the bottom of the pouch of Douglas. When suture is deemed too difficult, an adequate suprapubic drainage tube must be instituted with completely ample perivesical drainage to the site of the wound.

An indwelling catheter through the urethra has many drawbacks in the transport and handling of wounded

men and in warfare greatly augments the risk of severe urinary sepsis. When the bladder and pelvic rectum are both wounded, suture of each viscus must be performed. In injuries of the perineal rectum and the extraperitoneal part of the bladder, suture may be very difficult. In such instances adequate perineal, perivesical and suprapubic vesical drainage must be instituted. When stabilization and a more favorable surgical environment occur, a perineal rectovesical repair can be done.

The concussion rupture of the bladder most usually fragments the structure. In such instances all mucosa should be jealously preserved, and great caution should be used in removing any tissues near the rupture. The rapidity with which islands of mucous tissue regenerate and coalesce to form new bladder lining is frequently astounding.

Extraperitoneal wounds of an uncomplicated character produce blood in the urine, difficult urination and extravasation. There may be few symptoms at first, but under observation, if extravasation is occurring, suprapubic discomfort and a palpable mass appear. Wounds occurring in the buttocks, thighs, hips, perineum or genitalia with remote evidence of abdominal symptoms is suggestive of extraperitoneal rupture and should be carefully investigated. In extraperitoneal ruptures the urinary extravasation will follow the fascial planes.

Extravasation from a bladder rent occurring in the front may travel upward between the peritoneum and the abdominal muscles or, if the rent is more posterior, the extravasating urine may dissect extraperitoneally along one or both ureters, forming a bulging palpable mass in one or both flanks. Retrovesical extravasation may pass through the sciatic notch to the buttock, may pass through the obturator foramen to the thigh or follow through the inguinal canal to the scrotum. With infection supervening, fever, leukocytosis and evidence of sepsis quickly follow.

Necessary primary surgical intervention is best carried out at the advanced surgical hospitals at the front. With no evidence of intraperitoneal injury and adequate urinary drainage established, a "hands off" policy may be assumed until the patient reaches a more favorable surgical environment; otherwise, should there be apparent danger of extravasation, expeditious surgical intervention should be instituted by suprapubic tube and adequate regional drainage. The dictum should be supportive treatment and no more immediate surgical intervention than necessary.

THE TRAUMATIC CORD BLADDER

A second and equally distressing problem as it pertains to the bladder in warfare are spinal cord injuries and the bladder sequelae arising from them. Much desultory writing has been presented in urologic literature, with but little attempt at correlation.

Injuries to the spinal cord produce bladder paralysis by severing the continuity of the reflex arc controlling the act of voiding, and consequent urinary retention results. The bladder rapidly distends to such formidable size as to establish fear of rupture. If the injury is above the 11th dorsal segment, an overflow dribbling quite readily occurs; conversely, an injury below this level is likely to establish a spasm of the vesical sphincter. If the problem was merely that of the relief of urinary retention there would be no necessity for discussion. But, as the statistical records of the American and British hospital services in World War I amply testify, the problem is one of urinary tract infections.

The Manual of Military Urology of the American Expeditionary Forces urged a course of nonintervention in these bladders, assuming that the bladder would automatically care for itself (automatic bladder).

Young⁴ states "We have been unable to obtain accurate statistics as to how successful this was. In many instances we find that surgeons ultimately thought it necessary to provide suprapubic drainage or catheterization, intermittent or inlying, in order to relieve great vesical distention. It is impossible for us to find out what success this plan had in ultimately preventing the infection and ascending destruction of the kidneys in these cases."

Early British experience with the same procedure established that eventually 100 per cent of such cases became infected, and especially did those cases become rapidly infected when catheterization was done.

Sir Thompson Walker in his Hunterian lecture reported 450 cases of spinal injuries from which there were 179 deaths due to sepsis following overdistention and catheterization.

In my experience rarely did a patient with a spinal injury arrive at the base without having been catheterized from one to several times, and all with severe sepsis. The patients reaching the base hospital who fared best clinically were those who had had early suprapubic drainage, and even in those already severely infected suprapubic drainage with the attendant increased facility for antisepsis sharply reversed the mortality experience.

With the knowledge of this experience in World War I, a subsequent survey was made of a number of orthopedic and industrial surgeons in the country. Interestingly, every surgeon interviewed voiced the paramount importance of avoiding urinary tract infection, and for this reason, sixty-three surgeons resorted to the establishment of automatic overflow in all cases. Likewise for the same reason, fifty surgeons instituted an immediate continued regimen of intermittent catheterization, thirty-three an indwelling catheter and twenty-nine surgeons instituted an immediate or later permanent suprapubic drainage. Practically no answers could be obtained relatively to mortality from urinary tract infection complications. Only five surgeons stated that it was their practice to handle the complicating condition with a urologist as a consultant. With the knowledge that over 50 per cent of orthopedic and industrial surgeons interviewed in civil life are votaries of some type of catheter drainage and knowing as we do the catheter to be the grand executioner in a great number of these cases, a plea is made for the revival of Sir Thompson Walker's dictum of immediate suprapubic drainage.

Probably the most nearly ideal approach to these cases is detailed by Dr. Clyde Deming⁵ of Yale University Hospital. He states that:

Our procedure for having paralytic bladders due to a fractured spine is to open the bladder with a Kidd cystotome by the suprapubic route and drain as soon as possible.

We see all the paralytic bladder cases which come into our hospital. They are admitted to the orthopedic service, and the fractured vertebra is treated by an orthopedic surgeon. If, however, there is paralysis of the limbs, the patient is examined by the Neurological Service and if there is any indication for neurological surgery this is done by the neurological surgeons, such as decompression of the cord.

4. Young, Hugh H., and Davis, D. M.: *Young's Practice of Urology*, Philadelphia, W. B. Saunders Company, 1926, vol. 2, p. 695.

5. Deming, C. L.: Personal communication to the author, March 30, 1932.

We do not allow these individuals to develop an automatic bladder, as it has been our experience that all of these cases develop infection and that it is much better to drain the bladder before infection takes place, as the drainage can be done in a very aseptic manner without leakage and without much infection later on.

When these cases come to us with infection in the bladder we open and drain them immediately.

We have found that all paralytic bladders heal very nicely if we want them to. Of course, the position of the fracture makes some difference as to the handling of these cases, but we have felt that when a case is to have a long period of paralysis or continued paralysis it is much better to drain the bladder early than wait for infection. In this way, we can handle the cases without kidney infection and keep them in much better general condition.

SUMMARY

1. Wounds of the bladder are usually complicated and extremely dangerous.

2. Restorative procedures and the emergency surgery necessary should be done at front line hospitals, special attention to drainage and to the frequency of intra-peritoneal and intestinal injuries being given.

3. Necessary reparative procedures for complicating conditions and restoring the urinary tract to normal should be done at the base hospital.

4. Urologic consultation should be sought in all cases of cord bladder from spinal injury.

5. The cord bladder as the result of spinal injury should never be catheterized.

6. Previously catheterized and all infected bladders should have immediate suprapubic drainage.

7. In civil practice the experiences of bladder injuries of war can be adopted with great profit.

1015 Sharp Building.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. SCHOLL, MCIVER,
BYWATERS AND MUNGER

DR. W. F. BRAASCH, Rochester, Minn.: The incidence of renal injury in war probably is greater than the records would show. There are many cases with injury to various intra-abdominal organs, including the kidney, which never have been reported. Coincident injury of the kidney occurs most frequently with penetrating lesions of the intestine, liver, lower part of the thorax and the spleen. When it occurs in these cases the usual diagnostic signs and symptoms of renal injury may be of little value. Most of the patients are in shock, and the symptoms caused by lesions in other organs are predominant. The immediate mortality is great. The incidence of penetrating abdominal injury in which only the kidney is involved is comparatively rare. Routine inspection of the urine for evidence of hematuria is imperative in every case of intra-abdominal injury. If the patient cannot void, he should be catheterized. The usual methods of urologic diagnosis, which are available only at general hospitals, are not of much immediate help in many of these cases. Since most of the patients are in shock, the excretory urogram is of little or no value in visualizing the degree of injury. Cystoscopy rarely is indicated. The treatment of nonpenetrating renal injury such as may result from contusion and falls is quite different. With this type of injury the usual methods of investigation and treatment employed in civilian life may be used. Such injuries are not of common occurrence in the armed forces. Profound shock, which usually is observed with multiple intra-abdominal wounds, often is absent in spite of hematuria. Conservative treatment in these cases, as in civilian life, usually is advisable. There may be, however, specific reasons for surgical intervention, such as rapidly extending hematoma, severe pain or physical evidence of extensive renal injury. With every injury involving the lumbar and lateral abdominal areas the urine, voided or catheterized, should be examined. The extent of the renal injury frequently can be determined by a preliminary excretory

urogram. In many cases, however, the urogram will fail to give definite evidence of the extent of the lesion because of obscuring intestinal gas or inadequate visualization. The absence of any visualization of the renal pelvis in the excretory urogram does not mean necessarily that surgical intervention is indicated. Renal injury may be great enough to prevent temporarily excretion of the dye in the affected kidney but, after the reflex influence of injury has passed and the lesion is healed, the renal function may return to normal. If the excretory urogram is a failure and if the patient's condition becomes worse, cystoscopy with retrograde urography is advisable. I am inclined to agree with Sargent that no harm will result to the patient by employing cystoscopy with retrograde urography, and it frequently is the only way in which an exact diagnosis can be made. Necrotic muscle tissues apparently create a substance, probably myohemoglobin, which is highly toxic and damages the excretory renal tissues, causing symptoms of shock and uremia. Dr. Bywaters' statement that shock is not a clinical entity but a syndrome caused by a great variety of conditions would seem to be justified. His observation that serum potassium is increased and that electrocardiographic changes of potassium poisoning occur corroborates those made by Keith, King and Osterberg. Although the clinical data are not parallel, nevertheless the shock and uremia which follow instrumental perforation of the suprapubic or perineal tissues come to the mind of the urologist who has been unfortunate enough to observe such complications. Equally puzzling is the renal deficiency, with uremia, which not infrequently follows loss of a large amount of blood such as may occur with transurethral prostatic resection. In these circumstances usually there is no clinical evidence of shock, nor are there any subjective symptoms of uremia until late. However, the gradually mounting blood urea and the gradually diminishing urinary output indicate the renal lesion. The renal failure is progressive in many of these cases in spite of every effort made to restore renal balance and may terminate fatally; there is no hemoconcentration, nor does there seem to be any potassium imbalance until the later stages of uremia. Nevertheless, postmortem examination of the kidneys reveals a pathologic condition similar to that described by Dr. Bywaters: an acute nephrosis, as though some toxic substance had been liberated into the blood stream and, when excreted in the kidneys, caused profound renal damage.

DR. O. S. LOWSLEY, New York: These papers are particularly well prepared discourses on war injury and effect on the kidneys. Dr. Scholl has given an excellent picture of the pathology, symptoms and diagnosis of injury to the kidney, as well as treatment. He has mentioned the attitude which we take toward patients with a history of trauma to the kidney followed by hematuria. I wish to emphasize that watchful waiting is a much more dangerous procedure than operating under our present excellent aseptic technic, not necessarily because of immediate results but particularly as regards remote damage to the kidney. It has been proved that kidney damage, not necessitating an emergency operation, may result in permanent damage to the kidney, elevation of the blood pressure and great destruction of kidney tissue. With the benefit of ribbon-gut repair of traumatized kidneys proved on animals and human beings, there is no jeopardy to the patient's life by removing the clots and repairing the damage done to the kidney. Draining the kidney pelvis for a period of time will prevent extravasation of urine and subsequent damage to the glomeruli and tubules and thus prevent further damage. Every patient with gunshot wound of the kidney should be operated on as soon as the diagnosis is made. Dr. Bywaters has brought out an important point in connection with the kidneys of persons who have received crushing injuries to other parts of the body. Patients who recovered after such a severe type of injury showed a low urinary output. The first day there would be a rise in the blood urea nitrogen to 60 or even 100 mg. per hundred cubic centimeters; on the second day it will be normal. They are left with unimpaired renal function. Those who are more seriously damaged may have a blood urea nitrogen as high as 400 or 500 mg. per hundred cubic centimeters. On the critical period, on the seventh day, a diuresis occurs and is maintained for several days until the retained nitrogen is entirely secreted. Then the blood pressure falls to normal and the renal function

returns slowly to normal and it may take five months for the urea clearance figures to be normal. Damage to the compressed muscle in such severe cases is never completely repaired. In fatal cases, two thirds of the deaths occurred at the end of the first week, the majority on the sixth day. The potassium level in the serum increases sometimes to more than twice the normal upper level. The pathologic changes in the kidneys show swollen tense structures with foci of tubular necrosis most pronounced in the boundary zone. This damage seems to be due to the precipitation in acid urine with high salt concentration and hematin and subsequent blockage of the tubules. The treatment of such cases, according to Bywaters, consists first of administration of fluid in alkali and the usual treatment of shock in the form of morphine for pain and blood transfusions. Renal failure is treated by the use of diuretics as sodium bicarbonate and concentrated serum. Decapsulation has been advocated and insulin and dextrose may be valuable.

PENICILLIN TREATMENT OF SULFONAMIDE RESISTANT GONOCOCCIC INFECTIONS

IN FEMALE PATIENTS

PRELIMINARY REPORT

ALFRED COHN, M.D.

WILLIAM E. STUDDIFORD, M.D.

AND

ISAAK GRUNSTEIN, M.D.

NEW YORK

Several publications,¹ have already appeared on the subject of penicillin treatment of sulfonamide resistant gonococcic infections. These reports, however, dealt exclusively with infections in the male. The present report deals with the result of penicillin treatment of sulfonamide resistant gonococcic infections in 44 women.

All of the women included in this study were hospitalized for the purpose of penicillin treatment in the gynecologic service of Bellevue Hospital. After an initial follow-up of at least five clinical and bacteriologic examinations the patients were discharged with instructions to report at the clinic of the Gonococcus Research Unit, Department of Health, City of New York, for further observation.

CLINICAL MATERIAL

Forty-two of the 44 cases had failed to respond to at least 2 courses of 20 Gm. of sulfathiazole. The remaining 2 women had exhibited a definite hypersensitivity to sulfonamide and therefore were given penicillin treatment.

The presence of gonococcic infection was verified by smears and cultures performed at the laboratory of this unit. Infection of the cervix alone was reported

in 12 patients, of the urethra alone in 1 and a concurrent infection of the urethra and cervix in the remaining 31. Involvement of the adnexa was found in 15 patients. Four of the women were pregnant. The average duration of infection prior to penicillin treatment was 92.5 days (maximum nine months, minimum twenty-one days).

TREATMENT

Each 10,000 Oxford units of penicillin was dissolved in 2 cc. of sterile isotonic solution or distilled water. The penicillin was injected intramuscularly in the gluteal region. Injections were repeated at three hour intervals.

DOSAGE

The accompanying table represents the number of patients treated and the amounts of each single dose and the total dosage of penicillin administered at three hour intervals.

RESULTS OF THERAPY

All 44 patients were apparently cured by penicillin treatment. In 1 case, however, a relapse occurred on the second day following the termination of therapy. This patient had received only 50,000 Oxford units of penicillin; she became bacteriologically negative after subsequent treatment with an additional 100,000 Oxford units of penicillin.

Following penicillin treatment, daily clinical and bacteriologic examinations were performed. All the patients showed a reversal of their initial bacteriologic findings from positive to negative within twenty hours after the termination of penicillin therapy. Follow-up at Bellevue Hospital was continued for an average of 7.2 days, and an average of 5.8 bacteriologic examinations were performed on each patient. The additional average follow-up period in the clinic of the Research Unit was 38.4 days, and an average of 3.6 examinations were performed up to date. All the patients followed up (37) remained bacteriologically negative throughout this period.

No significant changes in the amount and character of the cervical discharge after penicillin treatment were observed. However, the urethral discharge in a number of cases decreased or disappeared completely. Among the 15 patients with adnexal involvement the inflammation subsided in 7 and remained the same in 5 others. In the remaining 3 an exacerbation of the adnexal involvement was observed following the use of penicillin. One of the 24 patients without any adnexal disease prior to penicillin treatment developed salpingitis following therapy.

The course of the pregnancy in 4 patients was affected in no way by the penicillin treatment.

Eleven of the 44 patients studied suffered from a concurrent infection with *Trichomonas vaginalis*, which remained entirely unaffected by this type of treatment.

In addition to the penicillin treatment of women there was 1 case of sulfonamide resistant gonococcic vaginitis in a child aged 5 years, who was given four single doses of 10,000 Oxford units of penicillin at three hour intervals (Children's Medical Service of Bellevue Hospital, Dr. James L. Wilson, director). This child promptly became negative and remained negative during a follow-up period of twenty-five days.

TOXICITY

The administration of penicillin in the recorded dosage produced no toxic effects. The only complaint mentioned by nearly all the patients was that following

F.; Ferguson, Charles; Buchholtz, M., and Van Slyke, C. J.: The Use of Penicillin Sodium in the Treatment of Sulfonamide Resistant Gonorrhea in Men, *Am. J. Syph., Gonorr. & Ven. Dis.* **27**: 525, 1943. Van Slyke, C. J.; Arnold, R. C., and Buchholtz, M.: Penicillin Therapy in Sulfonamide Resistant Gonorrhea in Men, *Am. J. Pub. Health* **33**: 1392, 1943.

the penicillin injection numbness or pain radiating from the site of injection in the gluteal region down to the thigh or to the ankle occurred. These symptoms lasted for only a few minutes.

COMMENT

Reviewing the results obtained thus far, it appears that a minimum total dosage of 75,000 Oxford units of penicillin is satisfactory in the treatment of sulfonamide resistant gonococcal infection in the adult female. If this observation is confirmed further, it will be possible to control sulfonamide resistant gonorrhea by one day treatment of ambulatory patients. The single relapse among a group of 9 women, each of whom had received a total dosage of 50,000 Oxford units of penicillin, points to a varying individual susceptibility to this agent. Smaller dosage of penicillin may prove adequate in many cases. This difference in the degree of susceptibility to the therapeutic action of penicillin has also manifested itself in *in vitro* experiments carried out by this unit.²

*Dosage of Penicillin Administered in Various Groups of
Sulfonamide Resistant Gonococcal Infections in
44 Adult Female Patients*

Group	Number of Patients	Single Dose	Number of Injections	Total Dosage
1.....	12	20,000 Oxford units	5 doses	100,000 O. U.
2.....	10	25,000 Oxford units	4 doses	100,000 O. U.
3.....	12	25,000 Oxford units	3 doses	75,000 O. U.
4.....	1	20,000 Oxford units	3 doses	60,000 O. U.
5.....	8	25,000 Oxford units	2 doses	50,000 O. U.
	1*	25,000 Oxford units	2 doses	50,000 O. U.
		25,000 Oxford units	4 doses	100,000 O. U.

* Only failure after total dosage of 50,000 Oxford units; responded to an additional total amount of 100,000 Oxford units.

SUMMARY AND CONCLUSIONS

1. Forty-two adult female gonorrheal patients who did not respond to at least two courses of sulfathiazole were treated with various amounts of penicillin. Two additional infected patients were also given penicillin because they were sensitive to sulfonamides.

2. Forty-three women of the total of 44 promptly became bacteriologically negative after treatment with penicillin and remained negative during the follow-up period.

3. Only 1 of a group of 9 patients showed a relapse following a total dosage of 50,000 Oxford units of penicillin; she responded to an additional total amount of 100,000 Oxford units of penicillin.

4. The bacteriologic reversal from gonococcus positive to negative took place as a rule within twelve hours following the termination of therapy.

5. A total dosage of 75,000 Oxford units of penicillin appears to be satisfactory in the treatment of sulfonamide resistant gonorrhea in the adult female. This therapy may be completed within a period of six hours.

6. A child aged 5 years with a sulfonamide resistant gonococcal vaginitis became bacteriologically negative after a total dosage of 40,000 Oxford units of penicillin.

7. No toxic effects due to the administration of penicillin were observed.

THE IN VITRO EFFECT OF
PENICILLIN

ON SULFONAMIDE RESISTANT AND SULFONAMIDE
SUSCEPTIBLE STRAINS OF GONOCOCCI

ALFRED COHN, M.D.

AND

IRMA H. SEIJO, B.S., M.T.

NEW YORK

The exceptionally powerful inhibitory effect of penicillin on the growth of the gonococcus *in vitro* has already been reported.¹ The current study was undertaken to evaluate these findings and to determine specifically whether or not there was any difference in the antibacterial action of penicillin against sulfonamide resistant and sulfonamide susceptible gonococcus strains. An attempt was also made to study the effect of combined "subtherapeutic" doses of sulfathiazole and penicillin on sulfonamide resistant strains. The object of this experiment was to see whether the combined antibacterial action of these two agents would be effective when the action of each individual agent was not sufficient to kill off the organisms.

TECHNIC

The technic followed in these test tube experiments was identical with that previously described for the *in vitro* differentiation of sulfonamide susceptible and resistant strains, with the only difference that penicillin² was substituted for sulfathiazole.³ The penicillin powder was diluted in sterile distilled water, and from this stock solution serial dilutions were prepared and added to the blood in such a manner that a dilution of 1 cc. of stock solution in 10,000 cc. of blood contained 0.176 Oxford Units per cubic centimeter. The various dilutions of penicillin used were 1:10,000, 1:100,000, 1:200,000, 1:500,000 and 1:1,000,000. In each experiment at least two and usually three or four different dilutions of penicillin were tested simultaneously. Control bloods without penicillin were included in every experiment and always showed satisfactory growth of the organisms.

EFFECT OF PENICILLIN ON SULFONAMIDE RESIS-
TANT AND SUSCEPTIBLE STRAINS

A total of 259 tests were performed on 55 sulfonamide resistant strains, and 132 tests were carried out on 27 sulfonamide susceptible strains. The accompanying table represents the inhibitory effect of the various penicillin dilutions on susceptible and resistant strains. It became obvious that with a 1:10,000 dilution of penicillin all of the sulfonamide susceptible and sulfon-

The laboratory work was aided by a grant from the United States Public Health Service.

L.; Meyer, K., and Chaffee, E.: Activity of Penicillin *in Vitro*, Proc. Soc. Exper. Biol. & Med. 50: 277, 1942. Herrell, W. E.; Cook, E. N., and Thompson, L.: Use of Penicillin in Sulfonamide Resistant Gonorrheal Infections, J. A. M. A. 122: 289 (May 29) 1943.

2. The penicillin used in these experiments was made available to us through the courtesy of Charles Pfizer & Co., New York. It was packaged in ampules each containing approximately 8,800 Oxford units.

3. Cohn, A., and Seijo, I.: Further Observations on the Correlation Between Clinical and *In Vitro* Reactions of Gonococcus Strains to Sulfathiazole, Am. J. Syph., Gonorr. & Ven. Dis. 27: 301, 1943.

amide resistant strains were killed off. However, as the dilution of the penicillin was increased, sulfonamide susceptible strains showed themselves to be relatively more inhibited by the antibacterial action of penicillin than sulfonamide resistant strains. For example, although a dilution of 1:200,000 killed off 53 per cent of the susceptible strains, it acted against only 38 per cent of the resistant strains tested with this dilution.

VARIATIONS IN INDIVIDUAL STRAINS

The susceptibility of different strains to penicillin was found to vary strikingly, so that some strains survived in a dilution which killed off most of the others and vice versa. A similar observation became evident in our clinical study on sulfonamide resistant gonococcal infections in female patients.⁴

COMBINATION OF SUBTHERAPEUTIC DOSES OF PENICILLIN AND SULFATHIAZOLE

Two sets of experiments were carried out, as follows: In the first, 11 sulfonamide resistant strains were grown in bloods containing both 3 mg. per hundred cubic centimeters of sulfathiazole and penicillin in a dilution of 1:200,000 or 1:500,000. In the second experiment 3 resistant strains were first grown in these same dilutions of penicillin for twenty-four hours and

tests an increase of the antibacterial action of penicillin became apparent, while in six others a decrease of this action was noted.

AGE OF PENICILLIN SOLUTION

Tests were carried out to determine if the aging of stock solution of penicillin kept in the icebox at 4 C. would weaken the in vitro potency of the antibacterial action of penicillin against the gonococcus. The inhibitory effect of serial penicillin dilutions of 1:10,000 to 1:1,000,000 prepared from these stock solutions was tested at weekly intervals for four weeks. The results indicate that, under the conditions mentioned, no essential variation of the potency of the various penicillin dilutions during this interval became noticeable.

SUMMARY

1. In a 1:10,000 dilution of penicillin representing 0.176 Oxford Unit per cubic centimeter all of the sulfonamide susceptible and resistant gonococcus strains were killed off.

2. With increasing dilutions of penicillin, sulfonamide susceptible strains were relatively more inhibited than sulfonamide resistant strains.

3. The susceptibility of different strains to penicillin varies strikingly in different dilutions.

Effect of Penicillin on Sulfonamide Resistant and Sulfonamide Susceptible Gonococcus Strains

Dilution of Penicillin.....		1:10,000		1:100,000		1:200,000		1:500,000		1:1,000,000

- - Antibacterial action. 0 No bacterial action.

then transferred to blood containing 3 mg. per hundred cubic centimeters of sulfathiazole. The growth of the gonococcus strains was not affected in either of the two experiments.

These observations lend further support to the current assumption that the two antibacterial agents attack the organisms in different ways.

DELAYED ADDITION OF PENICILLIN

While in previous experiments the drug effect was studied by adding drug and organisms simultaneously to the blood, the effect of penicillin added after the gonococcus strains were already growing for twenty-four hours was tested in a small series of experiments. The inhibitory effect of two penicillin dilutions (1:10,000 and 1:100,000) respectively on sulfonamide susceptible and resistant strains was found to be about 15 to 20 per cent less than when drug and organisms were added simultaneously.

ADDITION OF PARA-AMINO BENZOIC ACID TO PENICILLIN

The effect of para-amino benzoic acid added to various penicillin dilutions was studied, but no consistent results could be obtained. In the majority of tests performed (forty-two) the antibacterial action of penicillin against both types of strains was the same in the penicillin blood alone as in the penicillin blood containing para-amino benzoic acid. In seventeen other

4. The growth of sulfonamide resistant strains was not affected by the combination of "subtherapeutic" doses of penicillin and sulfathiazole.

5. The addition of para-amino benzoic acid to various penicillin dilutions did not yield consistent results as to the growth effect on the gonococcus strains.

6. The antibacterial action of dilutions of penicillin obtained from stock solutions which were kept for four weeks at icebox temperatures and tested at weekly intervals did not reveal any essential variation of its potency.

Room 1020, 125 Worth Street.

Medical Science and Irrational Fears.—In the matter of freedom from the fear of many epidemics, such as smallpox, the black death, yellow fever, diphtheria and typhoid, medical science has largely conquered helpless and irrational fear. Today fears of cancer, poliomyelitis, heart disease are widespread, but when their causes are more fully and generally known irrational fears will be relieved, even if their prevention and cure have not been solved. For example, in the epidemic of infantile paralysis in 1916 many towns and villages established shotgun quarantine against all transportation of persons under 16 years of age. In the 1890's similar quarantines were set up against all persons coming from yellow fever districts. Medical science has in large part removed such irrational fears even if it has not established unailing cures of these diseases or means of their prevention. We fear most those things which are mysterious, "the pestilence that walketh in darkness," the causes of which are unknown.—Conklin, Edwin G.: "The Doctor's Dilemma" of Medical Ethics in Peace and War, *Science* 99:187 (March 10) 1944.

Clinical Notes, Suggestions and New Instruments

A RAPID TREATMENT FOR SCABIES

LIEUTENANT (Jg) ALBERT H. SLEPYAN, MC-V(S), U.S.N.R.

Scabies, by its annoying and distracting itch, is the source of considerable wartime disability. All modern methods of treatment of scabies have as their ultimate aim the use of a substance easily applied, rapidly lethal to mites and eggs and nonirritating to the skin. This aim is now an urgent wartime goal, since the saving of sick days means more men at more guns. It is with this purpose in mind that the procedures here described were instituted at the U. S. Naval Training Station, Great Lakes, and Camp McIntire Dispensary.

Kissmeyer¹ in 1937 reported on Nielsen's rapid ambulatory treatment for scabies. He used benzyl benzoate, soft soap (B. P. 1932) and isopropyl alcohol of each equal parts. In 1942 Mellanby and his associates² applied the benzyl benzoate lotion with and without the bath and found the treatment 100 per cent effective. They concluded that benzyl benzoate was rapidly lethal to mites, which are killed within five minutes of contact away from the body. Roxburgh,³ making use of the newer wetting agents, using a 25 per cent solution of benzyl benzoate as an emulsion in water, using 2 per cent Lanette Wax SX. From the materials readily available the type of lotion presented in table 1 was derived and found most suitable.

The benzyl benzoate is gently poured over the Duponol C in the bottom of a jug.⁴ To this the 2.5 per cent aqueous solution of bentonite is added slowly without shaking. The emulsion is then agitated until all of the wetting agent is dissolved.

TECHNIC

On admission to sick bay the following routine was followed:

1. Remove all clothing, put in bag, either autoclave or send to laundry.
2. Shower, using soap freely. Scrub, with particular attention, the involved areas.
3. Paint entire body from ear-chin line down, covering all folds of body. Use paint brush with long firm bristles.
4. Let dry on skin. Repeat painting in five minutes.
5. Put to bed. Cover with at least two blankets, or sufficient to make patient warm. Keep in bed for four hours.
6. Shower, dry well. Apply calamine ointment if any irritation is noted.
7. Clean clothes.
8. Return to duty with instructions to patient to report for follow-up examinations.

Before the formula and technic were arrived at, the patients (group 1) were painted with equal parts of benzyl benzoate, soft soap, alcohol and water. Each patient was given three paintings at four hour intervals, put to bed for four hours, showered and sent to duty. This treatment, although 100 per cent effective, in all those followed fourteen days or longer, was disagreeable in several respects. The paintings were associated with considerable smarting and burning and a varying degree of irritant dermatitis, most bothersome about the scrotum,

which appeared shellacked after the first painting, resulting in desquamation of the skin of the penis and scrotum by the end of the tenth day.

Two patients who complained of swelling and edema of the penis required treatment with cold wet packs for a day before being fit for duty.

It was apparent that the alcoholic soap mixture produced too much post-treatment pruritus. A lotion making use of a wetting agent as an emulsifier³ was then tried (table 1).

Patients (group 2) were treated with the same routine as group 1. Smarting and burning were conspicuously diminished with this lotion. Although the post-treatment irritant dermatitis was diminished there was considerable dryness of the skin, particularly of the thighs, upper arms, lateral sides of the abdomen and the scrotum, necessitating soothing emollients at night. When this routine was found as effective as that of group 1, a third group, group 3, was started on a five hour routine. This proved most satisfactory. The irritant dermatitis was minimal and the efficacy was maintained (table 2).

In all three groups the patients were observed routinely on the third, seventh and fourteenth days after treatment. Those with simple pyodermic lesions were treated as for uncomplicated scabies. Most all of those cases responded to the paintings without further treatment; a few were given a 3 per cent ammoniated mercury ointment for several nights.

Number of recurrences of symptoms..	none	none	none

It is noteworthy that a goodly number observed between the fourteenth and twenty-eighth day exhibited relics of the infestation; namely, involuting papules, crusts, scars and pigmentation. These residuums at times superficially suggest recurrences; however, repeated potassium hydroxide preparations were negative. Further observation substantiated the fact that only the relics remained.

Four men were seen on the third day after treatment complaining of isolated new vesicles appearing on the webs of the fingers. A vesicle was removed and a sodium hydroxide preparation was examined. In each instance an egg was found undergoing what appeared to be fatty degeneration. The capsule was well defined, while the contents contained pycnotic, mosaic-like dark masses. Several of the vesicles were marked and observed on the tenth day and found dried and no longer pruritic. The parasitic remains found in scraping these areas were further shrunken.

Two patients were concurrently infected with pediculosis pubis. One of them had involvement of the axillary and abdominal hair. The treatment was gratifying in stopping the itching. No live pediculi could be found after the treatment. On the third, seventh and fourteenth day visits nits were plentiful but could be easily slid off the hairs. Twenty-one days after treatment there were no signs of parasitic infection. It was interesting to note that under the microscope the pediculus was killed almost immediately on being engulfed with a drop of the scabies lotion.

3. Roxburgh, A. C.: Treatment of Scabies, *Practitioner* 149: 228 (Oct.) 1942.

4. Duponol C is obtainable from E. I. du Pont de Nemours, Wilmington, Del. This product contains several alcohol sulfates, chiefly lauryl sodium sulfate, some myristol sodium sulfate, cetyl sodium sulfate and sarcyl sodium sulfate.

SUMMARY

A clean, simple, nonirritating five hour treatment for scabies has been developed. The time of the treatment has been reduced and the efficacy maintained. The use of benzyl benzoate as a scabicide is well established. Of the 189 patients followed longer than fourteen days, no recurrences were noticed. The lotion presented suggests further trial on patients with pediculosis pubis.

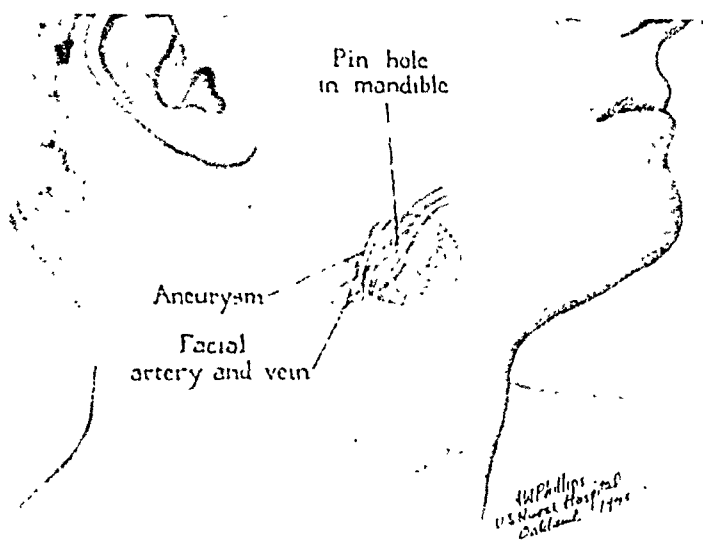

ARTERIOVENOUS ANEURYSM RESULTING FROM APPLICATION OF ROGER ANDERSON SPLINT

LIEUTENANT COMMANDER PAUL W. GREFLEY (MC), U.S.N.R.
AND

LIEUTENANT ALBERT H. THRONDSOEN (DC), U.S.N.R.

While it is admitted readily that the use of external pin fixation has a definite place in the management of fractures of the mandible, certain potential complications in its technical application may be overlooked. A patient recently under our care demonstrates a complication that we feel should be recorded.

A man suffered an oblique fracture through the right angle of his mandible. An early reduction was performed and the teeth were wired in occlusion. Because the mandible was eden-

Location of thrombotic arteriovenous aneurysm.

tulous posteriorly a Roger Anderson external pin fixation splint was substituted to stabilize the posterior fragment in the reduced position. The wires were removed after partial union to permit early motion and use.

At the time of application of the splint, one of the pins accidentally injured the underlying facial artery and vein. An immediate swelling developed that pulsated. The mass grew quickly to the size of a walnut. Pulsation continued for about one month, following which the mass gradually solidified but remained approximately the same size.

The splint was removed six weeks after application with evidence of good union at the fracture site. Three weeks later the tumor was explored. A thrombotic arteriovenous aneurysm was encountered, which was removed by resection between the ligated proximal and distal ends of the facial artery and vein. An uneventful convalescence followed its removal.

We feel that thoughtful preoperative planning will readily eliminate the likelihood of the future occurrence of this complication in the management of mandibular fractures. It should also be pointed out that the same principles should be observed in using external pin fixation apparatus in the treatment of fractures elsewhere in the body.

Special Article

AMERICAN HEALTH RESORTS

THALASSOTHERAPY

CHARLES I. SINGER, M.D.

LONG BEACH, N. Y.

AND

KENNETH PHILLIPS, M.D.

MIAMI, FLA.

These special articles on spa therapy and American health resorts were prepared under the direction of the Committee on American Health Resorts. The opinions expressed are those of the authors and do not necessarily reflect the opinion of the committee. These articles may be published later as a Handbook on Health Resorts.

Thalassotherapy is the utilization of ocean climate in preventing and treating disease.

Like many other sciences, it has gone through several phases of development from the empirical to the present day objective analytic research. The old Greek and Roman curators administered sea water as a laxative and used it in skin diseases. There are a few vague statements in Hippocrates as to the effectiveness of its external application in the form of showers and affusions; Plinius, Avicenna and later Savonarola made passing reference to the therapeutic use of sea water.

Richard Russell of England was the first to advocate sea bathing as a form of treatment in the mideighteenth century; fortunately he was able to persuade the reigning monarch to submit himself to "the cure." As a result, Brighton mushroomed as a fashionable seaside resort. In 1791 the Royal Sea Bathing Hospital was founded in Margate, England. Following the English rediscovery of therapeutic ocean bathing, colorful one man crusades for its general adoption were led in Europe by Barellai of Italy, Petrochaud of France and Benecke of Germany. These were the founding fathers of thalassotherapy, brought to its height of development in recent years by Haeberlin,¹ Kestner,² Krauel, Schaeke,³ and their co-workers in Germany.

In prewar Europe, hundreds of seashore sanatoriums with thousands of beds were located along the irregular coast line of Europe. Belgium, a small country with a seashore line 40 miles long, had over forty sanatoriums with 3,500 beds—a sanatorium on each mile of the seashore. The United States with 6,000 miles of coast line boasts but three noteworthy institutions—one each in Connecticut, New York and New Jersey.

An estimated 20 million people each year use the American seashore as a vacation ground without any planned climatic exposure or supervised daily regimen. This presents remarkable potentialities for future scientific development.

In order to discuss climatotherapy scientifically one must get acquainted with (1) the physical properties of the climate, (2) their biologic effect on the human organism and (3) their controlled application.

CLIMATIC PHYSICS

Climate is the sum total of meteorologic phenomena that characterize the average state of the atmosphere; it is a long range view on weather. Geographically, one distinguishes between arctic, temperate and tropical climates. Of geologic importance are high altitude, desert and seashore climates.

The vicinity of the ocean may have an influence on weather changes in an area extending 50 miles or more inland (maritime zone). In a smaller zone (up to 4 to 6 miles inland) the cooling effect of sea breezes can be generally felt (marine zone). Biologically the most important area is the vicinity of the beaches 50 to 100 yards from the water line. The latter, called the pelagic zone, is the one in which all the seashore climatic factors are most effective.

The three leading seashore climatic factors, each a complexity in itself, are air, sun and water.

Air.—"The sea air should be looked upon as remedy in itself," says Churchill's Medical Directory. "How a change of air can profoundly modify breathing, circulation, metabolism, cannot at present be explained, but many delicate children and invalids are as sensitive to the quality of air as are plants."

TABLE 1.—Pollen at Mitchel Field and at Long Beach

	Mitchel Field, L. I.	Distance 12 miles	Long Beach, L. I.
5,000 feet.....	6 pollens		33 pollens
4,000 feet.....	32 pollens		26 pollens
3,000 feet.....	28 pollens		12 pollens
2,000 feet.....	96 pollens		34 pollens
1,000 feet.....	74 pollens		97 pollens
750 feet.....	128 pollens		42 pollens
500 feet.....	116 pollens		102 pollens
250 feet.....	84 pollens		22 pollens
24 hour ground exposure.....	36 pollens		17 pollens

A satisfactory explanation of this statement can be found in an analysis of the qualities of sea air:

1. High oxygen content: 20.99 against 20.76 per cent in the continental air.
2. Relative freedom from dust, pollen, allergens, carbon monoxide and gaseous products of combustion.
3. High barometric pressure.

The sea breeze is an important feature of the summer along the seashore. It is a wind aroused and maintained by the difference of temperature between the inland and the ocean surfaces. It reduces the daily fluctuation of temperature by moderating the midday heat. It reaches shore in the middle of the forenoon with a velocity of 10 to 40 miles per hour and reduces the midday heat by 10 to 15 degrees Fahrenheit. It whips away fine, minute water particles from the crests of the waves breaking on the sand bars of the seashore. It carries this mist, containing chlorides, bromides, iodides in traces, about 50 to 100 yards inland (pelagic zone). The sea breeze maintains a sufficient degree of humidity, which seldom exceeds 75 per cent. The sea breeze is a powerful natural air conditioning mechanism of the seashore, purifying the air, producing desirable thermal equability and maintaining a convenient degree of humidity.

The iodine content of the sea air was determined on several occasions in Long Beach, N. Y., by a test sensitive to 10 micrograms per hundred cubic centimeters of iodide present. Filter papers which were exposed to the sea breeze in a circular frame 8 inches in diameter

contained 0.374 to 0.778 mg. of iodides at the end of twenty-four hours. The amount of iodides varied according to the heaviness of the surf and according to the velocity of the oceanic breezes which whip away fine sea water droplets from the wave crests. This phenomenon is a plausible factor in the apparent rarity of endemic goiter at seashores.

The pollen distribution in different air strata was determined above Long Beach, L. I., and Mitchel Field, L. I., on Sept. 22, 1936 with five minute airplane exposures. The results are shown in chart 2 and table 1.

Sun.—There is a distinct difference in the qualities of sunshine on seashores as compared with sunshine elsewhere. This difference is caused by the reflection of radiation from the water surface and the beach sand.

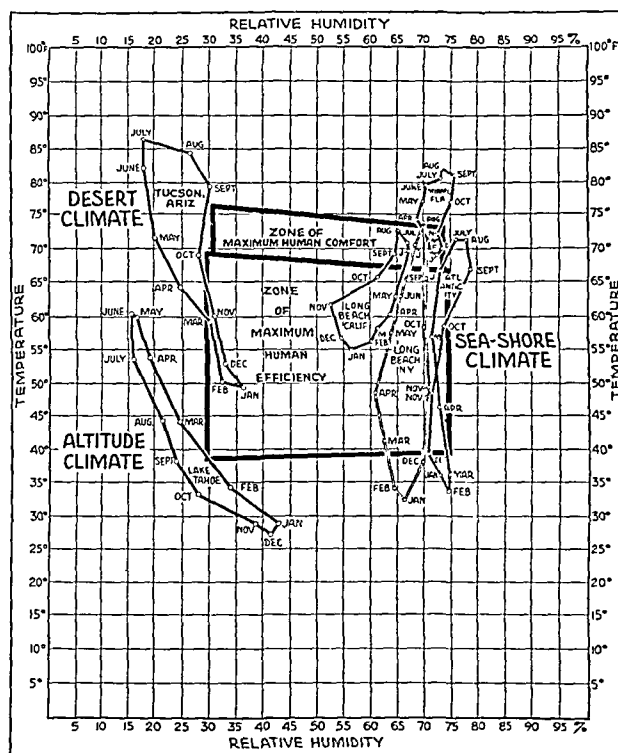

Chart 1.—Comparative climatogram. The climatogram, which covers all possible combinations of temperature in degrees Fahrenheit and relative humidity (per cent saturation), has projected on it the zone of maximum human comfort and the zone of maximum human efficiency. Silhouetted against these zones are the monthly temperature averages and the humidity averages of different localities representative of different climatic types. Characteristic types of climate represented are: Seashore climate: (a) Northern temperature: Long Beach, N. Y.; Atlantic City, N. J. (b) Southern temperature: Long Beach, Calif. (c) Subtropical: Miami, Fla. Desert climate: Tucson, Ariz. High altitude climate: Lake Tahoe, Nev.

The wide open spaces on the shore allow the full action of skylight radiation, which on partly cloudy days exceeds the amount of direct radiation. Campbell gives the same importance to the radiation from the ocean surface—the sea shine. Sandy beaches also produce reflex glare.

The humidity of the atmosphere does not weaken the biologically important wavelengths around 300 millimicrons, nor are they much lessened by dust, soot or oxidizable organic matter in the relatively pure air masses above the ocean. Quite the opposite happens to the rays arriving in longer wavelengths. Infra-red

rays are decidedly swallowed by the humidity. It is due to this phenomenon that the solar radiation of sea-shores is relatively cooler than the sunshine of high altitudes, which penetrates only dry air masses and loses little of its infra-red content. The mountain sunshine forewarns of ultraviolet damage by its warmth; the ocean sun fails to do so (Phillips).

Water.—Sea water is a compound salt solution of 2 to 4 per cent concentration containing mainly sodium chloride and potassium. It also contains magnesium, calcium, bromide, iron, phosphate, iodine, arsenic and strontium in traces. As it has been proved that no absorption of these mineral contents occurs, even with prolonged bathing, the effects of sea bathing must be attributed to (1) the temperature of the water, (2) the difference between the temperature of the skin and that of the water, (3) counterirritation of the skin by the salt content of the water, (4) mechanical stimulation by the waves of the surf, (5) degrees of exposure after bathing, (6) temperature and humidity of the air and (7) velocity of the sea breeze.

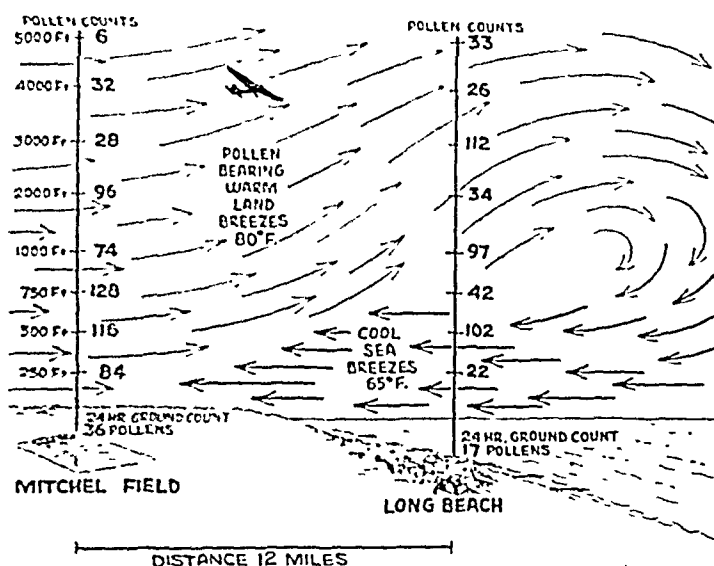

Chart 2.—Pollen distribution in different air strata above Long Beach, L. I., and Mitchel Field, L. I., on Sept. 15, 1936, as determined after five minute airplane exposures. Pollen counts are lower on sea level than in the altitudes. Pollen counts are lower on seashore than inland. The relatively low pollen count on sandy seashores is to be explained in four ways: 1. The cool sea breeze, blowing with a velocity of 12 to 18 miles, deflects the pollen bearing warm land breezes to higher altitudes; this is the chimney phenomenon. 2. The sea mist above the ocean surface completes the filtering of land burden breezes, which after depositing their pollen burden far out into the ocean return in the form of sea breezes. 3. There is a scarcity of vegetation on sandy beaches. 4. Flat seashores usually have marshy backgrounds without pollen-producing vegetation.

Minor Factors.—There are several minor factors cooperating in the marine cure—for instance, the iodine content of the air and the drinking water. The minor climatic factors, as the somewhat increased oxygen content of the air, the ozonization and the increased negative ionization, seem to be negligible, but one must consider that during a sojourn of eight to twelve weeks at the seashore the system constantly is exposed to the simultaneous effects of these factors.

CLIMATIC BIOLOGY

The biologic effect of a climate on the human organism depends mainly on its heat absorbing capacity. This heat absorbing capacity (expressed in calory square centimeter minutes) is influenced by a complexity of coeffective factors in the atmosphere. These factors are temperature, humidity, winds, barometric pressure and sunshine intensity.

Fundamentally, climatotherapy is the planned and supervised exposure to an atmosphere with a heat absorbing capacity different from that of the original habitat. This is reinforced by judicious application of heliotherapy and hydrotherapy.

Every human being has his own individual comfort zone within the range of which while resting and normally clothed he does not perspire and is not chilled. He feels comfortable when his production of heat is in equilibrium with the heat absorbing capacity of the environment.

If the heat absorbing capacity of the seashore is higher than that of the habitat of the person arriving, the climatic change will have a stimulating effect; if it is lower, a sedative effect.

The biologic effects of a stimulating climate result in increased conservation of heat and increased production of heat. This is effected by heightened cutaneous vascular tone and elevation of the basal metabolic rate. Sedative climates produce the opposite: vasomotor and metabolic relaxation.

Cutaneous Effects.—Life in cities, with its lack of exposure to open air and sunshine, and the heating and clothing of modern life harm the physical heat regulation. The skin becomes "domesticated." It loses its faculty for dodging sudden intensive changes in temperature by tonic contraction of the blood vessels of the skin—the physical regulation of heat. This mechanism has to render the well reacting skin similar to a poorly heat conductive leather coat. On confronting sudden changes of temperature the blood vessels of the domesticated skin give up their tone, the inner temperature drops, the person shivers and may catch cold. More than 50 per cent of the children newly arrived at the seashore react in this manner; after only six weeks at the seashore, less than 25 per cent. The lost regulation of heat is regained. The skin becomes acclimated, hardened. The temperature of the skin of these hardened children drops sharply, while their rectal temperature stays constant or increases after a sea bath.

The ice cube test reliably reflects the improvement in the thermic reacting ability of the skin during acclimatization.

The pigment changes (tanning) and the ergosterol production of the skin under the influence of solar exposure are well established facts. Histamine-like substances produced by the skin increase in the blood stream on exposure to cold. Their plausible purpose is to counteract the initial rise in blood pressure on the sudden dip in environmental temperature (open air exposure, bathing).

Effects on Mucous Membranes and Respiration.—The dust, soot and acrid impurities of the city air are missing at the seashore, which undoubtedly lowers the bronchiolar contraction, a reflex maintained by vagus effect. The relatively high degree of humidity in the sea air eases the activity of the ciliary epithelium in removing mucus and impurities. As a result, the flat, rapid breathing of the city dweller becomes deeper and slower. The vital capacity of the lungs of city children observed on seashores (Haerberlin, Singer) increased by about 500 cc. and the chest expansion up to 1½ to 3 inches after a two months vacation at the seashore.

First to be affected by external stimulation, the skin and mucous membranes represent the "receptor" organs of climatic change. The "conductors" of environmental influences from the skin and the mucous linings to central organs (the hemopoietic system and the

endocrine system) are the autonomous nervous system and the blood.

The existence of autonomous imbalance, the prevalence of vagotonia in domesticated newcomers at the seashore, the shift toward sympathicotonia after a few weeks of climatic stimulation can be demonstrated by biologic tests and by pharmacodynamic methods such as the oculocardiac reflex, Erben's test, the epinephrine pressor effect and the modified Muck test.

The role of the main regulator, that of "the pace-maker" controlling the process of acclimatization, has to be conceded to the endocrine system.

The sojourn at temperate seashores in the summer and fall and at southern shores in the winter and spring has a sedative effect. Open air exposure and especially ocean bathing sharply increase the metabolic rate and have to be considered stimulating. To illustrate this statement, the production and consumption of energy in some common occurrences at the seashore will be expressed in calories:

1. The energy producing level of an adult resting lightly dressed in an environmental temperature of 20 C. (68 F.) is about 100 kilocalories per hour.

2. The same person produces about 300 kilocalories per hour, walking with a speed of 4 miles per hour.

3. A 12 mile sea breeze of 20 C. temperature would absorb about 300 kilocalories per hour from the skin of the same (undressed) adult. He would shiver soon if vasoconstriction of the skin did not protect him.

4. As the heat conductivity of the water is twenty-three times as much as that of the air, ten minutes bathing would absorb about 400 kilocalories from the body if prompt vasomotor reaction of the skin did not sharply reduce this loss of heat.

Besides this easily demonstrable metabolic increase governed by the thyroid gland there are several other observations to indicate accentuated activity of the endocrine system; for example:

(a) Relatively sporadic occurrence of goiter at seashores.

(b) Latent toxic goiters becoming manifest as a result of excessive exposure to highly stimulating climatic effects.

(c) Delayed menses in young girls on climatic change (Haeblerlin).

(d) Spontaneous improvements in the dysmenorrhea of adult females often encountered on seashore vacations.

(e) Fluctuations of the blood sugar level of the healthy adult in the first few weeks on seashore.

(f) Increased hexosuria in diabetic persons after prolonged ocean bathing.

Hematologic Changes on Climatic Stimulation.—Changes in the blood during thalassotherapy reported by German,² French⁴ and Italian⁵ observers are somewhat contradictory. From their data reinforced by the observations of one of us (Singer) on a large group of children and on healthy adults the conclusions given in table 2 can be drawn.

During the first few weeks of a seashore sojourn, especially with exposure to air and surf bathing, definite hematologic changes can be observed with apparent regularity (acclimatization phase). In case of over-exposure to cool air and with prolonged and frequent ocean bathing this blood change will become exaggerated and will be accompanied by headache, malaise, nervous irritability, loss of sleep and appetite, and by a possible

flare-up of dormant chronic inflammations (negative phase, supersaturation, bath reaction).

Complete acclimatization is noted by a reversal of the hematologic findings of the first few weeks of climatic therapy. An increased stability in cell count and blood chemistry characterizes this postacclimatization phase. Even excessive exposures will fail to elicit a negative phase at this stage of sojourn (stabilization phase).

THALASSOTHERAPY

Rationale.—Medically we distinguish two types of climate: the stimulating and the sedative or protective climate. We consider a winter climate of a given locality to be sedative if its mean monthly temperature is above 55 F., enabling an all year round outdoor existence. Floridian and southern Californian shores fulfill this requirement. A winter sojourn on any other

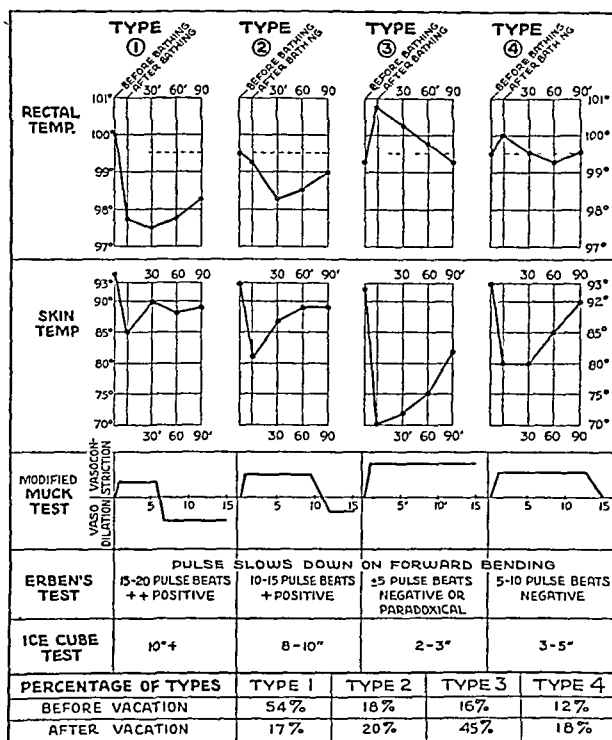

Chart 3—Systemic reactions to thalassotherapy: Type 1. Failure of the physical heat regulation. Domestication; relative vagotonia. Type 2. Transitional reaction type. Partial loss of heat regulation. Type 3. Corrected heat regulation. Relative sympathicotonia. Type 4. Ideal form of reaction: High autonomous stability.

Modified Muck Test. A 1:1,000 epinephrine solution is applied topically by means of an atomizer on the lower turbinate and septum on one side of the nose. In the blanched area a mechanical irritation is caused by scratching the area on a 1/2 inch long line with a blunt sound. The consecutive reactions are timed and recorded. Typical personal reactions: 1. Diffuse vasoconstriction (blanching) within thirty to sixty seconds. 2. Duration of vasoconstriction five to six minutes. 3. Reactive vasodilatation (reddening). 4. Red streak on the site of the mechanical irritation appearing usually one to two minutes earlier than the generalized vasodilatation. 5. Diffuse vasodilatation generally lasting more than ten minutes. Typical after season reactions: 1. Diffuse vasoconstriction within a half minute. 2. Duration of vasoconstriction ten minutes or more. 3. Occasionally a faint red streak starting at a later stage of observation. 4. Appearance of a white streak in the blanched zone, sometimes preceded by the aforementioned faint red streak. Persons displaying vasomotor rhinitis, hay fever and acute colds are not suitable subjects for this test. Whether this modified Muck test could be considered as a yardstick of the prevailing sympathicotonia and thus a possible indicator of the degree of the acclimatization cannot be definitely stated as yet.

Ice Cube Test. Delayed local hyperemia appearing later than ten seconds after two seconds' contact with an ice cube indicates poor thermoreacting ability of the skin.

American seashore is more or less stimulating. The summer on any seashore has protective, sedative qualities. Open air exposure and sun bathing are strong stimulating influences.

4 Picry, M. *Traite de climatologie biologique et médicale*, Paris, Masson & Cie 2: 905 1001, 1934.

5 Scerif, A. *Blood Changes in Marine Climate on the Adriatic*, Riv. idroclimat., talassol. e terap. fis. 48: 333 338, 1937.

The two main forms of thalassotherapy are (1) a sojourn in an ocean climate by (a) a stay of six to eight weeks at the seashore or (b) a prolonged ocean trip; (2) selective utilization of climatic factors under partial or complete (institutional) supervision.

The modalities of thalassotherapy are (1) sun, air, surf bathing and outdoor exercise; (2) brine baths or concentrated sea water baths for the treatment of scrofulosis and chronic inflammation of the female pelvis; (3) baths in heated sea water; (4) baths and packs with sea mud (liman) for the local treatment of chronic arthritis and fibrositis.

Under medical supervision climatic therapy can be coordinated with or molded into any form of physical, medical or surgical therapy, for example: (1) a mineral water regimen in gastrointestinal disorders; (2) inhalation therapy in chronic bronchial conditions; (3) surgical and orthopedic management of bone and peritoneal tuberculosis on seashores.

Medical science does not know of an actual optimal climate.

Indications and Contraindications.—The indications and contraindications of a given climate vary according to (1) season, (2) age, condition and constitution of the patient and (3) nature and stage of the chronic disorder to be influenced.

During the process of adaptation to a stimulating climate extensive fluctuations take place in the neurovascular, chemical and endocrine balance of the human system. A new threefold balance has to be found—adaptation to the environmental change. During this reorganization different preexisting chronic disorders of the system may be influenced—possibly eliminated.

The main biologic indications of the two medical types of climate are presented in table 3.

The majority of observers of seashore climatic effects agree that the following clinical conditions are beneficially influenced on seashores: In children: (1) chronic catarrhal processes of the upper respiratory tract and convalescence from influenza, pneumonia or whooping cough; (2) tuberculous involvement of cervical, bronchial and mesenteric glands and tuberculosis of bones, joints or the peritoneum; (3) constitutional imbalance (general debility and retarded development,

As to contraindications, there are practically none for sojourn at the southern seashores in any season. The same can be stated for temperate seashores in the summer and fall. The excessive stimulation present in the climate of northern shores, the strongly irritative factors in the stormy late winter of northern temperate

TABLE 3.—Indications of Two Types of Climate

Climatic Sedation on Seashores	Climatic Stimulation on Seashores
The climatic sedation is a good protective therapeutic measure. Its chief indications are:	Its chief indications are a large array of chronic diseases whose correction requires.
1. Constitutional defects (a) In the feeble aged (b) In the delicate child	1. Stimulation of the hemopoietic organs
2. Debilitating diseases, especially in persons whose constitution displays vasomotor or endocrine instability (a) Rheumatic heart disease (b) Chronic nephritis (c) Rheumatoid arthritis	2. Increased basal and mineral metabolism 3. Improved breathing mechanism 4. More effective physical heat regulation
	To be effective, climatic stimulation must be optimal in amount, avoiding ineffective underexposure and harmful overexposure

shores and surf bathing on any shore or in any season are contraindicated in (1) pulmonary tuberculosis, (2) hyperthyroidism, (3) severe neurosis and vasomotor disorders, (4) peripheral vascular diseases, (5) severe myocardial damage and (6) acute and subacute arthritis.

Failures for thalassotherapy can be ascribed to (1) faulty selection of the place or of the season, (2) disregard of contraindications, (3) insufficient exposure to climatic influences, (4) overstimulation of supersaturation and (5) poor habits of living continued at the seashore.

The following few suggestions are offered to enable avoidance of some common mistakes: The sojourn in southern climates necessitated by cardiovascular diseases should be planned to last through the whole winter. On returning to the north, it seems to be advisable to reduce the abruptness of climatic change by a few days stay in the pine belt of the Carolinas or in Virginia. On the last three days of a short southern vacation, extensive exposure to solar radiation is inadvisable as the resulting erythema will interfere with the heat regulating vasomotor mechanism of the skin on returning to the north. The negative phase (supersaturation) can be controlled by two days of complete rest and 2 or 3 grains (0.13 to 0.2 Gm.) of quinine plus 5 grains (0.32 Gm.) of bromides administered three times daily.

Thalassotherapy can be utilized to its optimal advantage only by cooperation between the physician of the city and the physician at the seashore. Whether climatic stimulation or sedation is needed, the family physician is the one who most probably will have to select the new climatic environment. In so doing he has to take into consideration the condition, the constitution and the social and financial background of the patient. One of his most important obligations to his patient is to provide him with the name and address of a reputable medical man on the site of the prospective vacation. Lastly he should provide the patient with a chart of the case history containing sufficient data to enable the recipient physician to comprehend the medical problem of the migrant. This medical identification card, this scientific passport will be useful in the vacation guidance, in the planning of therapy and in an emergency. The recipient specialist or general prac-

TABLE 2.—Changes in the Blood During Thalassotherapy

	Acclimatization Phase, First 2 to 4 Weeks	Stabilization Phase, Post- acclimatization

exudative diathesis, hypothyroidism, rickets); (4) microcytic types of anemia; (5) functional digestive and nervous disorders, or vagotonia. In adults: (1) convalescence; (2) nervous exhaustion; (3) chronic inflammations of the upper respiratory tract; (4) asthma or hay fever; (5) surgical tuberculosis; (6) chronic arthritis. In aged persons: (1) arteriosclerosis and hypertension; (2) chronic arthritis; (3) chronic bronchitis.

itioner should try his utmost to cooperate with the sender in acknowledging the arrival of the patient, giving his impressions of the case and outlining the therapy to be instituted. This friendly cooperation will enhance the after-care and will enable that long range planning which is so important in the treatment of the chronically sick. In this long range planning climatic therapy plays an important role.

Military and Public Health Importance of Thalassotherapy.—At a time when the utilization of every source of manpower is of extreme importance to the nation, thalassotherapy has a definite role in the war effort, first as an aid in military training through the "hardening" attained by surf bathing, second in the speedy rehabilitation of convalescent soldiers and third as an aid to bringing up to par persons with minor defects, i. e. secondary anemia, neurocirculatory asthenia and malnutrition.⁶

Southern seashores may play an important future role in the mass escape from the hardships of Northern late winter. Today's winter vacation is governed by vogue and hearsay evidence. Southern state authorities could build it up to a national institution by encouraging and supporting financially biologic investigations of the effects of these winter migrations.⁷ Northern seashores in the summer are ideal grounds for medically supervised vacations of American children. Exposure to climatic hardships builds a strong race; hiding from them breeds weaklings.

Wind protected open air schools in the fall on the beaches of the northern part of the land would contribute greatly to build a future American youth fit for war and fit for peace.

SUMMARY

Thalassotherapy is the utilization of ocean climate in preventing and treating disease. Its main factors—sun, air and water—act by their influence on the skin and the mucous membranes as receptor organs. The blood and the autonomic nervous system are used as conductors of their effects; thereby acclimatization is achieved, with the endocrine system acting as a possible "pacemaker."

The rationale of thalassotherapy includes (a) a sojourn at the seashore (a stay of six to eight weeks) and (b) selective utilization of climatic factors under partial or complete (institutional) supervision. There are indications and contraindications for climatic stimulation and for climatic sedation.

Thalassotherapy is of military as well as public health importance.

First Statistical Study of Disease.—From France came the first statistical studies of diseases. Of course there had been statistics of births and deaths before this time, but the great Parisian clinician Pierre C. A. Louis (1787-1872) was the first to show the value of purely medical statistics. By collecting the records of numbers of cases of different diseases he was able to show convincing proof of the efficacy, worthlessness or disastrous results of their treatment. Thus he helped to stem the torrent of bloodletting in which Broussais and others indulged, for he brought forward figures to show that in pneumonia, at least, bleeding was worse than useless. To Louis belongs the credit of showing that statistics are an important adjunct to the advancement of medical knowledge.—Haagensen, C. D., and Lloyd, Wyndham E. B. A Hundred Years of Medicine, New York, Sheridan House, Inc., 1943.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

AUSTIN E. SMITH, M.D., Secretary.

METAMUCIL.—A mixture containing about 50 per cent of powdered mucilaginous portion (outer epidermis) of blonde psyllium seeds (*Plantago ovata*-Forsk.) and powdered anhydrous dextrose, with sodium bicarbonate 0.2 per cent, monobasic potassium phosphate 0.25 per cent, citric acid 0.33 per cent and benzyl benzoate 0.04 per cent.

Actions and Uses.—Metamucil is intended as an adjunct in the treatment of constipation. It encourages elimination by the formation of a soft, plastic, water-retaining gelatinous residue in the lower bowel. The muciloid is also claimed to have a demulcent effect in the presence of inflamed mucosa. Metamucil has been mixed with barium sulfate to obtain more uniform dispersion of the barium for x-ray visualization.

Dosage.—Four to 7 cc. one to three times daily, each dose thoroughly stirred in a glass of water and followed by an additional glass of liquid. Children receive proportionate amounts according to weight and age. It is important that adequate fluids be ingested to assure a soft bulk. Metamucil should not be used carelessly so that a state of dependency is reached.

Tests and Standards—

Metamucil is a white to cream colored, slightly granular powder, possessing little or no odor and a slightly sour taste. A uniform suspension is formed when 10 Gm. of the powder is stirred rapidly into 250 cc. of water. As the hydration and swelling of the mucilaginous portion progresses, the mixture assumes a soft gelatinous consistency.

Place about 10 Gm. of metamucil in a dry 25 cc. glass stoppered graduate. Fill the graduate to the 25 cc. mark with a solution made by mixing 27 cc. of chloroform and 73 cc. of carbon tetrachloride. Stopper the graduate and mix the contents thoroughly. Set the graduate aside and observe the contents at the end of two hours a light colored layer appears at the bottom of the tube, approximately equal in volume to a brownish colored layer which appears at the top of the tube. Mechanically separate the layers formed in the graduate and dry the material at 80 C.; powder from the lower layer is soluble in water and responds to tests for dextrose, powder from the upper layer forms a mucilage with water and is microscopically identical with fragmented material obtained from the outer epidermis of blonde psyllium seed (*Plantago ovata*-Forsk.).

Transfer 50 Gm. of metamucil to a suitable flask and determine the moisture content by means of the method for moisture by toluene distillation described in the U. S. P. XII; the moisture content found is not more than 4 per cent.

Transfer exactly 20 Gm. of metamucil to a 150 cc. beaker, add 0.1 Gm. of decolorizing charcoal and 30 cc. of 80 per cent, v/v, ethyl alcohol preheated to 65-70 C. Stir the mixture thoroughly for three minutes and filter, while still warm, into a 50 cc. volumetric flask. Rinse the beaker twice with 7 to 9 cc. of warm 80 per cent alcohol and filter the rinsings through the residue on the filter paper, adding the washings directly to the volumetric flask. Cool to 25 C., add three drops of stronger ammonia water, fill to the mark with 80 per cent alcohol and mix the contents of the flask. Allow the mixture to stand for ten minutes and then determine the optical rotation of a portion of the solution in a 2 decimeter tube, using sodium light. Multiply the observed angular rotation by 21.7 to obtain the percentage of anhydrous dextrose present in the specimen taken; the amount of dextrose found is not less than 46 per cent nor more than 50 per cent.

G. D. SEARLE & Co., CHICAGO

Metamucil: 8 ounce container

U. S. patent 2,095,259 (Oct. 12, 1937; expires 1954). U. S. patent 2,132,484 (Oct. 11, 1938; expires 1955). U. S. trademark 317,704 (Oct. 2, 1934).

SULFANILAMIDE (See New and Nonofficial Remedies, 1943, p. 175).

The following additional dosage form has been accepted:

LEDERLE LABORATORIES, INC., PEARL RIVER, N. Y.

Sulfanilamide Surgical Powder (Sterile): 5 Gm. puffer tube.

SULFATHIAZOLE (See New and Nonofficial Remedies, 1943, p. 182).

The following additional dosage form has been accepted.

SATURDAY, APRIL 15, 1944

METABOLIC ASPECTS OF SHOCK

The hemodynamic disturbances in shock originate new conditions for cellular respiration and metabolism. All tissues and systems of the body suffer from a deficient blood flow and oxygen supply. Long and his group¹ report a series of investigations of the factors responsible for the metabolic disorders in shock. The sensitivity of liver and kidney to the anoxia accompanying hemorrhagic shock was tested by comparing the rate of respiration of slices of liver and kidney from normal rats and from rats in progressively severe states of shock. While the kidney did not show significant depression in use of oxygen even in most severe shock, liver proved to be exceedingly vulnerable to the deprivation of oxygen. The consumption of oxygen by slices of liver from severely shocked rats was about three times lower than that from normal rats. The depression in rate of use of oxygen by liver was closely parallel to the degree of severity of shock. Many of the chemical changes in the blood observed during the state of shock could be ascribed to the functional damage of the liver. There was an inverse correlation between the rate of oxygen consumption of the liver and the rise in level of amino acids of the blood which occurs in severe hemorrhage. Since deamination is to a great extent limited to the liver, hepatectomized animals constitute an appropriate preparation for the analysis of the role that the rate of breakdown of protein plays in the elevation of amino acids in the blood. In eviscerated rats with shock, Long and his colleagues found that the rate of accumulation of amino acids in the blood was much higher than that of eviscerated control rats. This observation indicates that an increased breakdown

of protein occurs in the peripheral tissues in shock. This affects mainly the muscles, which are, in addition to failure of the liver, responsible for the elevation of levels of nonprotein nitrogen and amino acids. Hence these levels may be used as an index of the damage suffered by the liver and muscles in shock.

The abnormalities in carbohydrate metabolism in shock were also studied by Long's group. While the blood sugar rises initially as a result of liberation of epinephrine as shown in adenodemedullated animals, in later stages of shock hypoglycemia of varying severity occurs. In hepatectomized shocked rats the rate of fall in blood sugar levels was distinctly greater than in the hepatectomized control rats. As the increased rate of utilization of glucose was associated with definite elevation of lactate and, to a smaller degree, of pyruvate, a shift from aerobic to anaerobic type of carbohydrate breakdown yielding less energy for molecule of glucose utilized was postulated.

Similar disturbances in carbohydrate metabolism had previously been reported by Govier and his colleagues,² who stressed the important role that the correction of the metabolic disorders may play in the therapy of shock. Thus dogs with a higher plasma level of thiamine were more resistant to the onset of shock than those with low thiamine in plasma. When thiamine was administered before bleeding, the blood pressure showed a constant tendency to return to normal after hemorrhage, enabling the animals to withstand more bleeding than the controls. Therapeutic administration of thiamine to dogs in which hemorrhagic shock had been induced prolonged significantly their survival time, as sugar, keto acids and lactic acid levels in the blood returned to normal.

These studies indicate the extreme importance of metabolic disorders in determining the course and outcome of shock. They also represent an important step in understanding the mechanisms responsible for shock and in correction of the abnormalities resulting from it.

VIRUS PNEUMONIA IN CATS

An infection of the respiratory tract in cats, variously called nasal catarrh, influenza or distemper, has been frequently observed in the Northeastern states. The main characteristics of this disease are sneezing, coughing and mucopurulent discharge from the eyes and nose. Although pneumonia usually cannot be demonstrated during life, necropsies often reveal grayish, densely consolidated areas in the anterior lobes. The disease is rarely fatal. The acute symptoms seldom persist for more than one or two weeks, although the debilitating after-effects usually last for over a month.

This pneumonic infection has been recently studied in detail by Baker¹ of the Department of Animal Pathology, Rockefeller Institute. Isolation of the causative agent was accomplished as follows: A 10 per cent emulsion of pneumonic tissues was prepared from sick cats, centrifuged for five minutes at 1,200 revolutions per minute and 0.05 cc. of the resulting supernatant fluid inoculated intranasally under light ether anesthesia into young mice. The mice became sick and usually died in from three to five days; necropsies showed a definite pneumonia, usually involving more than half of the lung tissues. Emulsions of these tissues were prepared in the same way as with the cat lungs and inoculated intranasally into other mice. In this way five strains of the cat infection have been established in mice. As a result of serial passage all five strains have increased in mouse virulence, death now occurring in two to three days after intranasal infection.

After the fifth and twentieth serial passages in mice the intranasal minimum lethal dose was determined for each strain. Groups of 5 animals each were then inoculated respectively with 10 minimum lethal doses intranasally, 10 intracerebrally, 50 intraperitoneally and 100 subcutaneously. All mice inoculated intranasally died in two to three days, while those inoculated by the three other routes did not develop signs of illness. Nevertheless the causative agent was present in suspensions of the brains of the mice inoculated intracerebrally and in the spleens of those injected intraperitoneally in sufficient quantities to give lethal pneumonia on intranasal instillation into other mice. Attempts to adapt the causative agent to extrapulmonary tissues by serial intracerebral or intraperitoneal passage gave negative results.

Although the mice inoculated intraperitoneally, intracerebrally or subcutaneously with the active suspensions did not develop signs of illness, they did acquire an almost solid specific immunity. Tested fourteen to twenty-one days later these vaccinated mice were fully resistant to intranasal instillation of massive doses of the infectious agent, control mice invariably succumbing to the infection.

Several groups of inoculated and noninoculated mice were placed together in the same cages. The inoculated mice were allowed to die before removal from the cages. Symptoms were not observed in the exposed mice, pneumonia was not found in half of the mice then killed for necropsy, and immunity could not be demonstrated in the remaining half, which were afterward tested by the intranasal route. The tests indicate that the disease is not readily spread by contact in mice, though contact transmission was readily demonstrable in cats.

A number of different animal species were tested for susceptibility to this infectious disease by intranasal instillation of doses roughly proportional to the body

weight. Mice, hamsters and young guinea pigs were highly susceptible, all dying from the disease. Cats, rabbits and adult guinea pigs showed only a mild infection, from which all recovered, necropsies revealing only mild pneumonic lesions as contrasted with the massive pneumonias in the highly susceptible species.

Cultures on blood agar and other specialized mediums failed to demonstrate a cultivable agent, suggesting that the causative agent is presumably a virus. Films prepared from pneumonic lungs revealed structures similar to the cytoplasmic plaques or elementary bodies developing in tissue cultures of psittacosis virus.² The unknown agent was readily cultivated in the yolk sac of fertile hen's eggs,³ where it also developed elementary bodies similar to those formed by the psittacosis virus. Centrifugation at 10,000 revolutions per minute for thirty minutes of suspensions containing both elementary bodies and the infective agent concentrated both the agent and the elementary bodies together. Both the infective agent and the elementary bodies failed to pass through a Berkefeld N filter. Complement fixation experiments using a suspension of partially purified elementary bodies as antigens gave positive results with the serums of recovered cats. These tests suggest that the elementary bodies are immunochemically identical with the virus.

Among Baker's clinically suggestive results are his tests of the possible viricidal action of immune cat serum. Although recovery serum gives positive complement deviation reactions with the elementary bodies, the serum is without demonstrable neutralizing effects on the virus. When inoculated intranasally into mice, the virus-serum mixtures are fully infective, suggesting that acquired immunity to the feline virus is due to cytologic rather than to humoral adaptations.

Tests of cats one to two months after full recovery showed that the virus was still present in infectious concentration in the nasal tissues. Inoculation of suspensions of ground nasal turbinates intranasally into mice gave lethal pneumonia. Cats that recover are demonstrably immune, since they do not show signs of reinfection when given multi-infective doses intranasally.

Numerous viruses have been previously described for cats. Lawrence,⁴ Hammon⁵ and others have reported a filtrable virus which produces fulminating leukopenia when injected intravenously. This virus, however, is not infective on intranasal instillation and is non-pathogenic for other animal species. The same virus had been previously described by Verge⁶ and others⁷ under the name of "cat enteritis." Two years ago

1. Baker, J. A.: *J. Exper. Med.* **79**: 159 (Feb.) 1944.

Blake⁸ discovered a pneumonia virus in kittens which is also noninfectious for mice and does not produce elementary bodies. The conclusion is drawn that Baker's virus differs from all feline viruses previously described. Presumably it is not the only virus capable of producing nasal catarrh and nonlethal pneumonia in cats.

VAGINAL SMEARS IN CARCINOMA OF UTERUS

The death rate from carcinoma of the female genital tract, according to Dublin,¹ is approximately 32,000 per year in the United States; of this figure four fifths, or 26,000, of the deaths annually are due to cancer of the uterus. This rate has remained practically constant during the past twenty-five years. This is tragic, since early diagnosis and modern treatment produce a high percentage of cures in carcinoma both of the fundus of the uterus and of the cervix. Papanicolaou and Traut² point out that the present difficulty in early diagnosis is our great dependence on the subjective symptoms of the disease to bring the patient to the physician. By the time the patient becomes sufficiently aware of discomfort to seek help, the disease is far advanced. Even when the patient is seen early in the course of the disease, the technic for making a positive diagnosis is not simple, as it involves biopsy followed by the procedures necessary for microscopic examination, all of which are time consuming and relatively expensive. Hoge³ questioned on admission to the hospital 91 patients in an effort to analyze the period of delay before treatment. On the average patients delayed four months before going to the doctor after the onset of symptoms, the doctor delayed three months before giving proper advice and there was another month of delay before treatment was begun.

Papanicolaou, after years of study of the normal and abnormal variations in the vaginal smear in women and in animals, became aware of the fact that carcinoma of the fundus of the uterus and carcinoma of the cervix are to some extent exfoliative lesions in the sense that cells at the free surface of the growth tend to become dislodged and subsequently to find their way into the vagina. He has developed a method for collecting the cellular debris, which is smeared on glass slides and stained in a particular way so that the various components may be studied. The method is simple and inexpensive and may be applied to large numbers of women. Papanicolaou states that cells pathognomonic of cervical and fundal carcinoma can be definitely recognized. The interpretation of smears calls for an intimate knowledge of the cytologic characteristics of the vaginal fluid.

Meigs and his associates⁴ studied the vaginal smears taken from 220 patients. Smears were taken from 153 women either because they were in the cancer age or because they had symptoms of vaginal bleeding or discharge; of these, 79 had biopsy, curettage or hysterectomy with negative tissue diagnosis for cancer. The remainder of these patients with negative smears did not present enough evidence for malignant disease to require operative procedure. Cancer cells were not found in the smears taken from these women. A histologic diagnosis of uterine carcinoma was made in 62 cases, 46 being carcinoma of the cervix; 40 of these cancers were epidermoid. Of the 46 cases with proved cancer of the cervix, positive vaginal smear diagnosis was made in 45, a percentage error of 2.2. Ten cases, or 22 per cent, were classified as early cervical carcinoma. Of 12 cases of endometrial cancer, 11 were diagnosed by vaginal smear, a percentage error of 8.3. Of 153 negative cases, positive smears were reported in 4, an error of 2.6 per cent. A cancer cell can be more readily identified in the vaginal smear than in the body fluid sediments or in the sputum. This increased accuracy in diagnosis is probably due to the fact that the cells of the vaginal fluid are in greater concentration and have suffered less degeneration. These authors do not feel justified in advising operation for uterine cancer solely on the evidence of a positive vaginal smear. The positive smears should be confirmed by biopsy or curettage. They consider the method as of significant value. The need for a systematic study of the entire smear and an experienced knowledge of cytology are emphasized. The method of vaginal smear examination appears to be an important addition to the early recognition of uterine cancer.

Current Comment

LEUKEMIA IN PHYSICIANS

Leukemia may occur in workers with radiation under conditions like those in which carcinoma of the skin due to radiation can arise. Exposure to x-rays under experimental conditions favors the development of leukemia in animals. Since high energy radiations may play a part in human leukemia, workers in the National Cancer Institute¹ have compared the incidence of leukemia in physicians and in the general population on the basis of the death lists of physicians in THE JOURNAL, the mortality reports of the United States Bureau of the Census and an unpublished compilation of the United States Public Health Service. The ratio of deaths from leukemia to deaths from cancer, the ratio of deaths from leukemia to total death rates, and death rates from leukemia were studied with the result that leukemia "was recognized approximately

1.7 times more frequently among physicians than among white males in the general population." The result is in accord with the increase in the incidence of leukemia in animals exposed to x-rays. Whatever the full meaning of the data at hand may be, the hazards of radiation require the strict maintenance of complete protection at all times.

INADEQUATE DIETS AND NUTRITIONAL DEFICIENCIES IN THE UNITED STATES

The Committee on Diagnosis and Pathology of the Food and Nutrition Board has reviewed material reported in widely scattered journals on the state of nutrition of the people of the United States.¹ An appreciable percentage of diets fail to meet more than 50 per cent of the recommended daily allowances of the Food and Nutrition Board, but many more diets are deficient by less than 50 per cent. This widespread prevalence of more or less deficient diets is associated with a high incidence of deficiency states, largely mild in intensity and gradual in its course. The problem thus created is both preventive and corrective. For prevention, production of sufficient food must be maintained and better distribution is required; judicious enrichment of appropriate foods may be advisable, and dietary education should be intensified and extended. For correction there is need for skill in detecting deficiency conditions and improved procedure for the treatment of such conditions. There has been some exaggeration of the benefits of optimal nutrition and much exploitation of the vitamins. This has retarded the proper application of the science of nutrition. However, knowledge of the relation of nutrition to health is being rapidly uncovered. The evidence now available, incomplete though it may be, leads to but one conclusion: that "there is a real difference as measured in terms of growth development and general health record between optimum and just adequate nutrition; and that every practical effort should be made to apply this knowledge in the interest of human welfare."

ANTITOXIN IN PLANT MATERIAL

Discovery of a hitherto unsuspected antitoxic factor in numerous plant materials is currently reported by Woolley and Krampitz¹ of the Rockefeller Institute. The discovery was a by-product of research on the toxic properties of glucoascorbic acid, a homologue of ascorbic acid having the same structural relationship to dextrose that ascorbic acid has to xylose. Given by mouth, this homologue apparently "blocks" ascorbic acid synthesis and utilization in cotton rats and mice, causing the characteristic symptoms of scurvy as seen in animal species susceptible to that disease. Inhibition of the action of vitamins by closely related chemical

homologues is not new, since "homologue blockade" is well established in bacteriology.² This, however, is the first demonstration of a similar phenomenon in higher animals. Woolley and Krampitz found that, when 5 per cent glucoascorbic acid is added to their routine highly purified basic diet, growth is inhibited in both rats and mice, followed by diarrhea, subcutaneous hemorrhages and rapid loss of weight, death usually occurring within three weeks. Oral or subcutaneous administration of ascorbic acid will not prevent or cure this scurvy-like syndrome. If, however, instead of 5 per cent glucoascorbic acid being added to the routine highly purified basic diet the same amount of the homologue is added to a mixture of natural rations, no scurvy-like symptoms develop. There is apparently some factor in natural plant materials that neutralizes or otherwise prevents "homologue toxicity." Dehydrated young grass was found to be the plant material of highest prophylactic or therapeutic value, with fresh cabbage a close second. The antitoxic factor in dehydrated grass is not destroyed by cooking.

CONSTITUTIONAL PRECOCIOUS PUBERTY

According to Novak,¹ genetic factors and endocrine mechanisms control the onset and development of the puberal processes. Precocious puberty and menstruation in females are more frequently dependent on an abnormal genetic constitution than on endocrine tumors or cerebral lesions acting by way of the hypothalamus and hypophysis. In the diagnostic search for the cause of precocious puberty, granulosa cell tumor of the ovary is considered as the first and most likely possibility. However, this tumor has been shown to be an extremely rare condition. In more than 60,000 patients examined in the Johns Hopkins department of gynecology only 1 instance of granulosa ovarian tumor was registered. Constitutional precocious puberty, in which the early development of the puberal phenomenon is not produced by any demonstrable underlying pathologic change, is considered by Novak the commonest form of precocious puberty. This author reports 9 cases of this syndrome in which tumor of the ovaries, adrenals or pituitary could not be demonstrated. A careful follow-up of these patients failed to detect any evidence of endocrine disturbances, neoplastic growth or cerebral involvement which would be expected to occur were these cases due to these factors. Constitutional precocious puberty is characterized not only by the development of puberal changes which were entirely normal except for the early age at which they appeared but also by the occurrence of the ovulatory menstrual cycle as evidenced by the finding of corpus luteum in 3 cases in which exploratory laparotomy was done. Hence it seems likely that many or all cases of abnormally early pregnancy that have been reported may have been instances of constitutional precocious puberty.

MEDICINE AND THE WAR

In this section of The Journal each week will appear official notices by the Committee on War Participation of the American Medical Association, announcements by the Surgeons General of the Army, Navy and Public Health Service, and other governmental agencies dealing with medicine and the war, and such other information and announcements as will be useful to the medical profession.

ARMY

ARMY FACILITIES AT FORT MEADE, SOUTH DAKOTA, TRANSFERRED TO VETERANS ADMINISTRATION

The War Department announced recently that the facilities of Fort Meade, South Dakota, will be transferred to the Veterans Administration on or before April 15 for use by the agency in treating sick and wounded veterans. This will be the first of several anticipated transfers by the Army of installations which at present are not needed for training because of troop movements overseas. Decision to permit the use of such army camps by the Veterans agency was reached some time ago at a meeting between Lieut. Col. Brehon Somervell, commanding general, U. S. Army, Army Service Forces; Brig. Gen. Frank T. Hines, chief of the Veterans Administration, and Major Gen. Norman T. Kirk, Surgeon General, U. S. Army. Fort Meade, an old regular army cavalry installation, can accommodate 2,031 men. caretaking detachment of approximately 150 personnel is stationed there at present, but all War Department personnel will be transferred on assumption of responsibility by the Veterans Administration.

APPOINT OPTICAL ADVISORY BOARD

The Office of the Surgeon General, U. S. Army, recently appointed a temporary board to be known as the Optical Advisory Board, to provide assistance in developing policies relating to the Spectacle Program and to provide for expediting decisions involving technical considerations. The board will consider such questions as may be referred to it and will meet at such times as may be requested by the officer in charge of the optical program, Lieut. Col. Walter H. Potter. Members of the board are:

Dr. William Thornwall Davis, 927 Farragut Square N.W., Washington, D. C.
Dr. Conrad Berens, 477 First Avenue, New York.
Col. Fred H. Thorne, M. C., Keesler Field, Mississippi.
Col. Burr N. Carter, M. C., Surgeon General's Office, Washington, D. C.
Lieut. Col. Walter H. Potter, Sn. C., Surgeon General's Office, Washington, D. C.

Capt. Kenneth A. Short, M. A. C., will act as liaison officer. Any questions on which board advice is desired may be submitted through Captain Short, who will report the findings or recommendations of the board.

LIEUT. HELEN E. WHARTON APPOINTED CHIEF NURSE OF FIFTH ARMY

The War Department recently announced the appointment of 1st Lieut. Helen E. Wharton, Army Nurse Corps, as chief nurse of the Fifth Army. She will be responsible for administration of nursing affairs on the scene of Fifth Army Medical Corps activities at and near the Italian front, which was formerly conducted from headquarters of the North African theater. As chief nurse, Lieutenant Wharton will be responsible for assignment of officers of the Army Nurse Corps serving with Fifth Army units in Italian combat zones and at base hospitals. She is a veteran of the Italian campaign, landing as chief nurse of an evacuation unit shortly after invasion troops secured their positions last September, and was aboard a hospital ship bombed in the bay of Salerno. Later she worked with other army nurses and doctors to restore the unit's hospital facilities and rescue patients after a tornado struck the hospital area.

Before joining the Army Nurse Corps in 1942, Lieutenant Wharton was assistant director of nursing at the New York Psychiatric Institute, New York. She is a graduate of the nursing school at Michael Reese Hospital, Chicago, with which volunteer unit she underwent training at Camp Blanding, Florida, and went overseas in April 1943.

MONTHLY MEETING OF MEDICAL OFFICERS AT ARMY MEDICAL CENTER

At the monthly meeting of medical officers in the Washington area held at the Army Medical Center, March 20, Col. J. E. Ash spoke on "Outline of the Functions and Facilities of the Army Medical Museum and Institute of Pathology," Capt. Frank H. Netter discussed "Medical Arts of the Museum, Particularly Its Application to the Training Program and to Prosthesis and Plastic Surgery," and Capt. Ralph P. Creer delivered a slide talk on "Museum and Medical Arts Service." A portfolio on first aid treatment program for enlisted men of the line and latex material used in training enlisted men of the Medical Department in emergency medical treatment was demonstrated after the meeting.

REDUCTION OF FRACTURES DURING FLUOROSCOPIC EXPOSURE

Since there are a few army hospitals which employ x-ray fluoroscopy during the reduction of fractures, the War Department has recently issued the Technical Bulletin of Medicine No. 22, in which it is recommended that, since this is one of the most dangerous uses of x-rays, lead impregnated gloves should be worn during the reduction of fractures under fluoroscopic exposure. Arrangements can easily be made with the x-ray department of any hospital for rapid film processing near the operating room, which will make possible control films to check position of fragments during reduction. These films can be processed and shown to the surgeon within two to five minutes after exposure.

BOARD ON DECLASSIFICATION OF RESEARCH AND MEDICAL REPORTS

A board of officers was recently named to consider all categories of classified technical medical and research reports and make recommendations to appropriate authority through the Surgeon General for declassification of reports when such change of classification is regarded as desirable. The board consists of the following officers:

Brig. Gen. Stanhope Bayne-Jones, chairman.
Col. Roger C. Prentiss, M. C.
Lieut. Col. William C. Menninger, M. C.
Lieut. Col. Frank R. Dieuaide, M. C.
Major Michael J. DeBakey, M. C.
Major Harold F. Dorn, Sn. C.
Major Harold M. Horack, M. C., secretary.

CAPT. CHARLES L. COGBILL JR. MISSING

Capt. Charles Lipscomb Cogbill Jr., formerly of Rochester, N. Y., has been reported missing in action in Italy since January 30. Dr. Cogbill had been serving overseas since November 1942 with the medical detachment of an infantry division. He graduated from Vanderbilt University School of Medicine, Memphis, in 1941 and entered the service in the fall of 1942.

ARMY PERSONALS

The commanding general of the Army Air Force Eighth Fighter Command announced the appointment of Major Louis Levine, formerly of Brooklyn, as commander of the base hospital at his station. Dr. Levine was commissioned as a first lieutenant in the Medical Corps July 12, 1942, and his exceptional ability earned him rapid promotion. He graduated from the University of Glasgow Medical Faculty in 1935.

Major Irving Graef, on leave of absence from the New York University College of Medicine, where he was associate professor of pathology, has been appointed director of the Medical Research Laboratory at Dugway Proving Ground, Tooele, Utah. This laboratory is an installation of the Medical Division Office of the chief of Chemical Warfare Service. Dr. Graef graduated from Cornell University Medical College, New York, in 1926 and entered the service Dec. 16, 1940.

Col. Floyd L. Wergeland, executive officer of the Medical Replacement Training Center, Camp Barkeley, Texas, since December 1942, has been named director of the Training Division, Surgeon General's Office. Dr. Wergeland succeeds the late Col. Frank B. Wakeman as director of training on the staff of Major Gen. Norman T. Kirk, Surgeon General of the Army. Dr. Wergeland is a Regular Army officer. He

received his degree in medicine at the College of Medical Evangelists, Loma Linda, Calif., in 1932 and entered the service in 1933 as a first lieutenant.

Brig. Gen. Percy J. Carroll, who was recently awarded the Distinguished Service Medal (*THE JOURNAL*, February 26, p. 580) for his role in safely evacuating wounded from the Philippines and subsequent achievements in the Southwest Pacific and the Far East, has been appointed commander of the new 1,500 bed Vaughan General Hospital at Hines, Ill.

Col. Frank H. Dixon, who has been stationed at Second Army headquarters in Memphis, Tenn., was recently designated as Third Service Command surgeon to take charge of all medical, dental, veterinarian, nursing and sanitary activities at installations in Pennsylvania, Maryland and Virginia. Dr. Dixon graduated from Indiana University School of Medicine, Bloomington, in 1911 and entered the service in 1914.

GRADUATE MEDICAL ADMINISTRATIVE OFFICERS

The thirtieth class of the Camp Barkeley Medical Administrative Corps Officer Candidate School graduated on March 15. Brig. Gen. Roy C. Heflebower, school commandant, presented the diplomas and commissions.

NAVY

LIEUT. HARVEY F. KREUZBURG AWARDED SILVER STAR MEDAL

Lieut. Harvey F. Kreuzburg, formerly of Washington, D. C., was awarded the Silver Star Medal "for conspicuous gallantry and intrepidity as medical officer of a U. S. destroyer in action against enemy Japanese forces in the South Pacific Area on Aug. 21, 1943. Although seriously wounded in the left arm during an air attack on his ship by enemy planes, Lieutenant Kreuzburg steadfastly ministered to his injured comrades with thorough skill and efficiency until severe loss of blood forced him finally to assume the less hazardous task of directing medical aid. By his selfless devotion to duty, his professional integrity and heroic perseverance, Lieutenant Kreuzburg undoubtedly saved the lives of many men who otherwise might have perished." Dr. Kreuzburg graduated from Georgetown University School of Medicine, Washington, in 1937 and entered the service March 7, 1942.

LIEUT. FAY B. BEGOR AWARDED NAVY CROSS

Lieut. (jg) Fay B. Begor, Medical Corps, U. S. Naval Reserve, was recently awarded the Navy Cross posthumously. The citation accompanying the award read as follows: "For extraordinary heroism and devotion to duty as Medical Officer aboard an Infantry Landing Craft when that vessel was disabled by a near miss from a Japanese bomb on Sept. 4, 1943. After the crippled ship was beached at Japanese occupied Lae on the island of New Guinea, Lieutenant (junior grade) Begor calmly continued his ministrations to the wounded in the face of repeated Japanese bombing and strafing attacks until he was killed by enemy fire. His courageous spirit of self sacrifice in rendering service to others in time of extreme peril was in keeping with the highest traditions of the United States Naval Service. He gallantly gave his life for his country." Dr. Begor graduated from McGill University Faculty of Medicine, Montreal, in 1941 and entered the service Sept. 1, 1942.

LIEUT. COMDR. CLARK N. COOPER COMMENDED

Lieut. Comdr. Clark N. Cooper, formerly of Waterloo, Iowa, has been cited for "outstanding performance of duty" by Vice Admiral Frank J. Fletcher, commander of the North Pacific Force. The commendation reads "For meritorious service as senior officer of the U. S. S. *Saint Mihiel* during and subsequent

to the assault on enemy held Attu Island. Lieut. Comdr. Clark N. Cooper, MC-V(S), United States Naval Reserve, was continuously on duty day and night, supervising the handling of and operating on the battle casualties received directly from the assault forces. His leadership, devotion to duty and professional skill were responsible for the excellent medical treatment received by personnel suffering from battle wounds and frozen feet. His conduct throughout was in keeping with the highest traditions of the naval service." Dr. Cooper graduated from the State University of Iowa School of Medicine, Iowa City, in 1928 and entered the service Sept. 19, 1942.

NAVY NURSE CORPS

The President recently signed H. R. 2976, the bill that gives actual rank to members of the Navy Nurse Corps during the period ending six months after the conclusion of the war. Heretofore they have had only relative rank. The enacted law places the nurses on a level with the officers of the Navy, Marine Corps and Coast Guard.

Congress recently passed an amendment to the Bolton Act which enables the Navy to participate in the education of students who are members of the United States Cadet Nurse Corps. The plan is to accept annually approximately 600 cadet nurses who are in the last half of the senior year for supervised practice in certain naval hospitals. At the end of the senior cadet practice they will be returned to their home schools for graduation. After passing their state board examinations the cadets will be eligible to make application for acceptance in the Nurse Corps of the Navy. This is a war measure only and will terminate with the last class of students to start their nursing education before the end of hostilities.

NEW NAVAL HOSPITALS TO BE CONSTRUCTED

The House Naval Affairs Committee, in a general public works authorization bill, reported recently an authorization for appropriation of \$42,071,750 for the construction of new naval hospitals and additions to existing facilities, to provide 20,100 additional beds. In its report on the bill the committee pointed out that on completion of the current fiscal year 1944 a total of 60,000 naval hospital beds will be available. The committee further stated that "based on statistics compiled from actual occupancy, first eighteen months of the war, and applied to the personnel, dispersion, peakload requirements and other factors known for 1945, a total of 80,000 beds in naval hospitals will be required to meet hospitalization needs in that year."

MISCELLANEOUS

HOSPITALS NEEDING INTERNS
AND RESIDENTS

The following hospitals have indicated to the Council on Medical Education and Hospitals that they have not completed their house staff quota allotted by the Procurement and Assignment Service:

(Continuation of list in *THE JOURNAL*, April 8, page 1068)

ALABAMA

Norwood Hospital, Birmingham. Capacity, 246; admissions, 5,755. Mrs. Ross E. Roberts, R.N., Superintendent (interns).

CONNECTICUT

Lawrence and Memorial Associated Hospitals, New London. Capacity, 291; admissions, 4,844. Mr. Richard J. Hancock, Administrator (interns).

IOWA

Mercy Hospital, Cedar Rapids. Capacity, 179; admissions, 3,862. Sister Mary Mercy, R.N., Superintendent (interns, residents).

MASSACHUSETTS

Wesson Memorial Hospital, Springfield. Capacity, 112; admissions, 2,898. Mr. James M. Dunlop, Superintendent (1 intern—August 1).

NEBRASKA

Lincoln General Hospital, Lincoln. Capacity, 213; admissions, 4,574. Mr. Robert B. Witham, Administrator (interns).

NEW YORK

Auburn City Hospital, Auburn. Capacity, 240; admissions, 6,844. Mr. Jerome F. Peck Jr., Acting Superintendent (assistant resident—August 1).
Meadowbrook Hospital, Hempstead. Capacity, 275; admissions, 5,085. Dr. A. J. McRae, Superintendent (2 interns—October 1).
Knickerbocker Hospital, New York City. Capacity, 200; admissions, 3,634. Mr. B. E. Foss, Administrator (5 interns).
New York City Hospital, New York City. Capacity, 880; admissions, 7,531. Dr. Beatrice Katz, Deputy and Acting Medical Superintendent (1 intern, residents—dermatology, neurology, etc., ear, nose, throat).
Highland Hospital, Rochester. Capacity, 266; admissions, 5,249. Dr. George B. Landers, Director (3 interns—September).

NORTH CAROLINA

Park View Hospital, Rocky Mount. Capacity, 125; admissions, 3,194. Mr. J. L. Melvin, Superintendent (mixed residencies).

OHIO

St. Alexis Hospital, Cleveland. Capacity, 220; admissions, 7,702. Sister Mary Elzearia, R.N., Superintendent (residents, interns).

TENNESSEE

St. Joseph Hospital, Memphis. Capacity, 316; admissions, 9,746. Sister M. Sponsaria, Superintendent (2 interns, resident).

WISCONSIN

Luther Hospital, Eau Claire. Capacity, 176; admissions, 4,377. Mr. N. E. Hanshus, Superintendent (intern, resident).
Madison General Hospital, Madison. Capacity, 234; admissions, 6,472. Miss Grace Crafts, Administrator (interns, residents—August, September, October).

STUDY CIVILIAN DISTRIBUTION OF
PENICILLIN

The Chemicals Bureau of the War Production Board announced recently that, with 95 per cent of new plant construction under the penicillin program begun last June having been completed and 90 per cent of the operating facilities delivered, no further major expansions will now be approved. Only minor adjustments in approved projects necessary for the elimination of production bottlenecks will be considered at this time. However, the War Production Board stated that it may be necessary to grant a limited amount of priority assistance to individuals with original processes for making penicillin. Members of WPB's Penicillin Producers Industry Advisory Committee are now studying proposals for exchanging technical and patent information and have been asked to make recommendations on civilian distribution.

At a recent meeting of the committee, members of a subcommittee named to study the civilian distribution problem reported that any definite recommendation would be premature at this time. The supply situation is expected to become clear soon, it was said, and more time was asked to consider the problem. Chemicals Bureau officials said that the subcommittee had been asked to make recommendations on how civilian dis-

tribution should be handled when penicillin is available to the extent of some 10 billion units or more a month. Various proposals for distribution were advanced for discussion. Under one of these allocation through the National Research Council would be continued for suitable critical cases in which there is jeopardy to life for a limited number of serious but noncritical cases, and for research. Members of the industry suggested to WPB officials, however, that until such time as more than 10 billion units a month is available, rigid control of civilian distribution would be necessary to prevent black market operations and indiscriminate use of penicillin.

CASUALTIES OF U. S. ARMED FORCES
SINCE OUTBREAK OF WAR

The Office of War Information reported on March 22 the number of casualties of the United States armed forces from the outbreak of the war, totaling 165,061. This total, combining the latest available War and Navy Department reports, includes 38,846 dead, 58,964 wounded, 35,521 missing and 31,730 prisoners of war. Of the prisoners of war, 1,894 have died in prison camps, mostly in Japanese occupied territory.

The War Department report (as of Feb. 29, 1944) lists army casualties totaling 123,054. Of this number 21,014 were killed, 48,260 wounded, 26,464 missing and 27,316 prisoners of war. Of the wounded 25,688 have returned to active duty or been released from the hospital. The casualties include 12,506 Philippine Scouts. Of these 469 were killed and 747 wounded. The others are assumed to be prisoners of war.

The Navy Department report (as of March 22, 1944) shows casualties whose next of kin have been notified totaling 42,007, made up of 17,832 dead, 10,704 wounded, 9,057 missing and 4,414 prisoners of war.

SUBSTANDARD DIET IN THE NETHERLANDS

In a recent release from the Netherlands Information Bureau, New York, the Dutch medical delegate to the United Nations Relief and Rehabilitation Administration conference at Atlantic City last November stated that the caloric content of the weekly ration in the Netherlands for April 1943 was 32.6 per cent below standard, animal protein 62.8 per cent, calcium 57.7 per cent, phosphorus 57.7 per cent, vitamin A 85 per cent, vitamin D 96 per cent and vitamin C 37 per cent. This means that the Dutch people are not consuming sufficient milk, bread, butter, meat, cheese, sugar, vegetables, oranges, lemons and eggs. In this connection Dr. Christian Goette, head of the Dutch-Nazi Medical Front, stated that, "in regard to the general health of the population, it must be said that resistance has been decreased as a result of the long duration of the war and that the number of infectious diseases has increased. This applies particularly to venereal diseases and tuberculosis. I wish it were possible to improve the nutrition of our youth, because undernourishment is spreading."

WINTHROP CHEMICAL COMPANY ADDS
WHITE STAR TO E PENNANT

The Winthrop Chemical Company, Inc., New York, was recently awarded a white star to be added to its E flag, in recognition of continued "meritorious service on the production front." The Winthrop Chemical Company is the country's largest supplier of atabrine.

MULTIPLE VACCINES IN GERMANY

According to NPD of February 15 (Germany), German science has discovered a double vaccine, equally effective against scarlet fever and diphtheria, which is already being used in practice. Even a quadruple vaccine has been produced which renders people immune against typhoid, cholera and paratyphoid A and B bacilli.

ORGANIZATION SECTION

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Change in Status.—Public hearings have been scheduled before a subcommittee of the House Committee on Appropriations on the budget estimate for funds to continue the obstetric and pediatric program for the wives and infants of servicemen. The hearings will be held on April 27 and 28.

Bills Introduced.—H. R. 4445, introduced by Representative Bolton, Ohio, proposes to authorize temporary appointment as officers in the Army of the United States of members of the Army Nurse Corps, female persons having the necessary qualifications for appointment in such corps, female dietetic and physical therapy personnel of the Medical Department of the Army, exclusive of students and apprentices, and female persons having the necessary qualifications for appointment in such department as female dietetic or physical therapy personnel. H. R. 4519, introduced by Representative Fish, New York, proposes an appropriation of \$1,000,000 to provide seeing eye dogs for certain blind veterans. H. R. 4533, introduced by Representative Tolan, California, contemplates the creation of a Chiro-

practic Corps in the Medical Department of the Army. H. R. 4554, introduced by Representative Davis, Tennessee, would authorize the appointment of x-ray technicians as commissioned officers in the Medical Corps of the Army and the Medical Corps of the Navy.

STATE MEDICAL LEGISLATION

New Jersey

Bills Introduced.—S. 156 and A. 295 propose to enact a separate chiropractic practice act and to create an independent board of chiropractic examiners to examine and license applicants for licenses to practice chiropractic.

Rhode Island

Bill Introduced.—S. 210 proposes to authorize the governor to appoint a special blood plasma bank commission to study the feasibility of establishing blood plasma banks in the several counties of the state for such persons as in the judgment of their attending physicians need blood plasma.

WOMAN'S AUXILIARY

New Jersey

The second meeting of the executive board of the New Jersey auxiliary for 1943-1944 was held in the executive offices of the Medical Society of New Jersey at Trenton recently. After a business session the executive board and the presidents of the county auxiliaries were served a buffet luncheon. Following the luncheon Miss Agnes Ohlson of the United States Public Health Service spoke on the Cadet Nurse Recruitment Program. Miss Wilkie Hughes, executive secretary of the New Jersey Council for War Service, spoke on the New Jersey aspects of this program.

Mrs. F. G. Wandell, chairman of Hygeia, reports that over 400 high schools and other educational institutions subscribe to *Hygeia*.

Atlantic County auxiliary held a card party for the benefit of the service men of the England General Hospital March 14 at the Madison Hotel in Atlantic City.

A health meeting sponsored by the Essex County auxiliary and the Contemporary Club of Newark was to be held March 21. Dr. Benjamin Saslow spoke on "Nutrition in Wartime."

The superintendent of the Passaic public schools spoke on "Juvenile Delinquency" at a recent meeting of the Passaic County auxiliary.

The Atlantic County auxiliary met recently at the Madison Hotel, and Miss Arreta Watts of the du Pont Company spoke on "How Chemistry Is Meeting Our Needs Today."

Essex County devoted its January meeting to a discussion of pending legislation. At the February meeting of the Hudson County auxiliary \$50 was given to the Red Cross. At the January meeting of the Camden County auxiliary, held at the home of Mrs. Haines Lippincott, the members were urged to support the coming cancer drive. Rev. H. O. Wyatt, formerly a missionary to India, spoke on "Present Day India."

New York

Mrs. Leslie Sullivan, president of the New York auxiliary, was guest speaker at the annual luncheon in Albany recently. She discussed the Wagner-Murray-Dingell bill.

Albany County auxiliary has a membership of 128 women. A speakers' bureau has been formed with 7 women as speakers,

and over a thousand women have had pending legislation explained to them. At the January meeting Dr. Robert Korn, epidemiologist of the New York State Health Department, spoke on "Tropical Diseases and Their Effects on Public Health." In April the auxiliary plans to collect medical supplies for the Medical and Surgical Relief Committee of America, Inc., New York City.

Nassau County auxiliary made dressings for advanced cancer patients recently; they had a Christmas party for the small patients at the Nassau hospital. Miss Yolanda Lyon of the Bureau of Public Relations of the state society spoke on methods of defeating the pending socialized medicine bill.

Texas

Mrs. A. B. Pumphrey, state president of Texas, in an article in the January issue of the *Texas State Journal of Medicine*, gives briefly the major items of interest to the auxiliary which were discussed at the meeting of the executive council of the state medical association at San Antonio recently.

OFFICIAL NOTES

DOCTORS AT WAR

Radio broadcasts of Doctors at War by the American Medical Association in cooperation with the National Broadcasting Company and the Medical Department of the United States Army and the United States Navy are on the air each Saturday at 4:30 p. m. Eastern war time (3:30 Central war time, 2:30 Mountain war time and 1:30 Pacific war time).

The titles and guest speakers for the next three programs are as follows:

April 15. "Decks Aflame."

Speaker, Capt. French Moore (MC), U.S.N., Washington, D. C.

April 22. "New Lease on Life."

Speaker, Col. Augustus Thorndike, M. C., U. S. Army, Washington, D. C.

April 29. "Winds That Kill."

Speaker to be announced.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ARKANSAS

Personal.—Dr. and Mrs. John Forrest McKnight, Bradley, observed their fiftieth wedding anniversary February 21.—Dr. Frances C. Rothert, Camden, has been appointed acting director of the division of maternal and child health in the state department of health, effective February 1.

State Medical Meeting in Little Rock.—The Arkansas Medical Society will hold its annual convention at the Marion Hotel, Little Rock, April 17-18, under the presidency of Dr. Samuel J. Allbright, Searcy, and with the Pulaski County Medical Society acting as host. Among the speakers will be:

- Dr. Henry E. Mobley, Morrilton, Surgical Management of Hernias.
- Dr. Arthur Neal Owens, New Orleans, The Applications of Fundamental Principles in the Treatment of Burns.
- Dr. Ira F. Jones, Fort Smith, Caudal Anesthesia.
- Dr. Donovan C. Browne, New Orleans, Cardiospasm: Its Medical Management.
- Dr. Nicholas T. Hollis, Little Rock, Newer Methods of Treating the Mentally Ill.
- Dr. Arthur C. Curtis, State Sanatorium, Tuberculosis Control Program in Arkansas.
- Dr. Rawley M. Penick Jr., New Orleans, The Diagnosis and Treatment of Various Arterial Aneurysms.
- Dr. Carl A. Rovenbaum, Little Rock, Tumor Clinic of the University of Arkansas School of Medicine.
- Dr. Edgar J. Easley, Little Rock, A Brief Summary of the Modern Concepts of Acquired Syphilis.
- Dr. Ludolf N. Bollmeier, Hot Springs National Park, How to Differentiate Emotional Glycosuria from Diabetes Mellitus.

CALIFORNIA

Typhoid in 1943.—There were 167 cases of typhoid reported in California last year, none of which gave substantiating evidence of having been water borne. Forty cases were traced to 14 proved carriers, 9 carriers were responsible for 1 case each and 1 carrier caused 3 cases, according to *California's Health*. Three carriers were the sources of 2 cases each. One carrier was responsible for an outbreak totaling 24 proved cases, 22 of which were recorded in 1943 and 2 in January 1944. This group of 24 cases was in Indians who attended two supper dances where the carrier served food. The second largest group of cases reported last year was in a state institution, where 7 cases were reported. There were 5 cases in one family, with 4 secondary to the first case. Eleven cases were diagnosed in California, but the patients were either ill when they arrived from other states or countries or they were taken ill within four days after their arrival. Two other patients contracted their infection while traveling through more than one county during the incubation period of the disease. It was therefore impossible to allocate these 13 cases to any single locality of California. One group of 3 cases of typhoid occurred among employees of a slaughterhouse, but the source could not be determined. There were six groups of 2 cases each, three groups of 2 cases, each due to a carrier, two groups of 2 cases, each with source undetermined, one group of 2 cases, with the second case secondary to the first. Out of the total of 167 cases recorded there were only 7 known secondary cases. There were 28 typhoid carriers recorded in California last year, 7 of whom were transfers from other states. Two carriers were reported previously as cases, but in 1943 they were determined to be carriers. Four carriers were revealed in individuals who were hospitalized for other reasons but who, on examination, were found to be carriers. Fourteen carriers were the sources of typhoid cases reported in 1943, and 1 carrier was the source of a case in 1940 which was recorded in 1943. No carriers were revealed in the course of food handlers' examinations.

CONNECTICUT

State Medical Meeting in Bridgeport.—The one hundred and fifty-second annual meeting of the Connecticut State Medical Society will be held at the Central High School, Bridgeport, May 2-4, under the presidency of Dr. George M. Smith, Pine Orchard. Among the speakers on the program will be:

- Dr. Francis G. Blake, New Haven, Penicillin.
- Dr. Edward A. Schumann, Philadelphia, Obstetrical Experiences.
- Dr. Homer F. Swift, New York, Rheumatic Fever.
- Dr. John H. Foulger, Wilmington, Del., The Principles of Preventive Medicine in Chemical Industries.

- Dr. Herbert C. Miller Jr., New Haven, Erythroblastosis Fetalis: What Is It?
- Dr. Thomas A. C. Rennie, New York, National Planning for Psychiatric Rehabilitation.
- Dr. James M. Cunningham, Hartford, Some Comments on Psychiatric Rehabilitation.
- Dr. John C. Leonard, Hartford, Some New Developments in Medicine.
- Thomas J. Duffield, B.S., New York, The Value of Uniform Records.
- Dr. Varaztad H. Kazanjian, Boston, Plastic Surgery Following Burns.
- Captain Howard B. Sprague (MC), U. S. Naval Reserve, A Navy Doctor in the South Pacific.
- Dr. Louis H. Bauer, Hempstead, N. Y., The Council on Medical Service and Public Relations of the American Medical Association.
- Dr. Kalci K. Gregory, Providence, R. I., Meningococcus Infections.
- Dr. Edward J. Whalen, Hartford, Chemotherapy in the Treatment of Nasal Sinus Disease.
- Dr. Maynard C. Wheeler, New York, The Measurement and Treatment of Strabismus in Children.
- Dr. Albert Oppenheimer, Laconia, N. H., Disease of the Spine.

A special meeting will be held Wednesday afternoon to organize a woman's auxiliary. Mrs. Eben J. Carey, Milwaukee, president of the Woman's Auxiliary of the American Medical Association, will, among others, discuss "The Purposes of the Woman's Auxiliary." The annual dinner at the Hotel Stratfield will be addressed by Governor Raymond E. Baldwin, Hartford, and Rev. Father Alphonse J. Schwitalla, dean, St. Louis University School of Medicine, St. Louis. The Connecticut Occupational Therapy Association will be addressed during the state society meeting by Mrs. Winifred C. Kahmann, OTR, Washington, D. C., on "Occupational Therapy in Army General Hospitals" and Ensign Harriet M. Jones, OTR, New York, Occupational Therapy Program in a Naval Hospital." A meeting of medical examiners will be addressed by Dr. Walter W. E. Jetter, Boston, on "Postmortem Recognition of Biochemical Disturbances." The Women's Medical Society will also convene during the session.

DISTRICT OF COLUMBIA

Personal.—Dr. James L. Hall was recently appointed superintendent of Freedmen's Hospital, succeeding Dr. John W. Lawlah, dean of the Howard University College of Medicine, who had been serving in both capacities.

Woman Dies from Rabies—Pasteur Treatment Ineffective.—The death of a woman at Gallinger Municipal Hospital, March 17, occurred five months after she had been bitten by a rabid dog. Newspapers reported that the reason the Pasteur treatment proved ineffective may have been that the woman suffered multiple bites about the head.

Army-Navy Night.—The Medical Society of the District of Columbia and its woman's auxiliary sponsored an "Army-Navy Night" on March 24. Addresses were given by Dr. Fred R. Sanderson, president, Medical Society of the District of Columbia; Vice Admiral Ross T. McIntire, Surgeon General of the U. S. Navy, and Lieut. Gen. Alexander A. Vandergrift, the commandant of the United States Marine Corps.

Clinic for Children with Cerebral Palsy.—A new consultation clinic for children suffering from cerebral palsy has been opened by the District of Columbia Society for Crippled Children at its headquarters, 1220 New Hampshire Avenue N.W., Washington. The clinic will be open one day a month and have facilities for about 25 consultations at each monthly session, the services to be free of charge. Dr. Winthrop M. Phelps, medical director of the Children's Rehabilitation Institute, Baltimore, and counselor on cerebral palsy for the National Society for Crippled Children, will supervise the clinic. According to *Medical Annals of the District of Columbia*, Dr. Phelps, formerly professor of orthopedic surgery, Yale University School of Medicine, New Haven, has established clinics in nine states and is now medical director of the state cerebral palsy program of the New Jersey Crippled Children's Commission.

KANSAS

Francisco Memorial Foundation.—A fund is being collected at the University of Kansas School of Medicine to establish the Francisco Memorial Foundation in honor of Dr. Clarence B. Francisco, Kansas City, Mo., professor of clinical surgery at the university, who died on February 23. The fund was started by medical students and faculty members, and it is hoped to accumulate sufficient funds to erect a student union building on the medical school campus in Kansas City. The building would house the medical library, a cafeteria, a recreation center, postgraduate facilities, a dormitory and rooms for visiting physicians. Dr. Francisco, who graduated at the University of Kansas School of Medicine in 1907, became associated with it in 1910.

Course on Cardiac Disorders.—A postgraduate course on cardiac disorders will be conducted April 15-23 under the auspices of the Kansas Medical Society, the University of Kansas School of Medicine and the Kansas State Board of Health.

The lectures will be given by Dr Chauncey C Maher, associate professor of medicine, Northwestern University Medical School, Chicago, and Dr. George A Walker, assistant professor of pathology, University of Kansas School of Medicine. Sessions will be held in Kansas City, April 15-16, Parsons, April 17-18, Salina, April 19-20; Wichita, April 20-21, and Topeka, April 22-23. Topics to be discussed will include thyrotoxicosis and heart disease, anatomical pathology of the heart, cardiovascular renal diseases and congestive heart failure, pathologic anatomy and physiology of hypertension, electrocardiograph in clinical heart disease, heart disease in the surgical patient and heart muscle reserve.

MARYLAND

License Restored.—The license of Dr. Cliff P. Berger, Washington, D. C., to practice medicine in Maryland was restored on February 2. The action was taken after Dr. Berger had received a pardon from the governor of Maryland and because of recommendations from numerous physicians who had been associated with him.

MICHIGAN

The Hickey Lecture.—The annual Hickey Lecture of the Wayne County Medical Society was delivered at a joint session April 3 with the Detroit Roentgen Ray and Radium Society. Lieut. Col. Joseph C. Bell, M. C. A. U. S., and Major Gilbert W. Heublein, M. C. A. U. S., gave the lecture on "Diagnostic Roentgenology in an Army Hospital During the Present War."

Grant for Research in Penicillin.—A grant of more than \$19,000 to the state health department laboratory for research in penicillin production methods is included in the public health bill voted during the recent special legislative session. *Michigan Public Health* believes that the state health department laboratories may be able to develop a means whereby the product can be manufactured at a cost which is practicable and is distributed on a statewide scale.

MISSOURI

State Medical Meeting in Kansas City.—The eighty-seventh annual session of the Missouri State Medical Association will be held at the Municipal Auditorium, Kansas City, April 23-25, under the presidency of Dr. Andrew W. McAlester Jr., Kansas City. Among the speakers on the program will be:

- Col. John T. King, M. C. A. U. S., Heart and Hypertension
- Dr. Peter Heinbecker, St. Louis, Etiology of Hypertension
- Dr. Drew W. Luten, St. Louis, The Heart in Hypertension
- Dr. Edward Massie, St. Louis, Management of the Hypertensive Patient
- Dr. A. Morris Ginsberg, Kansas City, Psychogenic Factors in Hypertension
- Dr. Henry K. Ransom, Ann Arbor, Mich., Abdominal Incisions
- Dr. Roland S. Kieffer, St. Louis, Nutritional Problems
- Dr. William B. Kountz, St. Louis, Special Problems of Poor Surgical Risks, Especially Age
- Dr. Charles F. Sherwin, St. Louis, Selection of the Anesthetic
- Dr. Edward L. Keyes, St. Louis, Sulfonamide Drugs as an Adjunct to Surgery

On Monday evening a banquet will be held at the Hotel Muehlebach in honor of past presidents of the association, at which the speakers will include Rev. Father Alphonse M. Schwitalla, S. J., dean, St. Louis University School of Medicine, St. Louis, who will discuss "The Position of Medical Education in Federalized Medicine." A general meeting Tuesday will be devoted to a series of panel discussions on traumatic surgery, gastroduodenal lesions, abnormal obstetrics and diabetes. A talk on the "Treatment of Leukemia with Radioactive Phosphorus" by Dr. Edward H. Reinhard, St. Louis, will conclude the meeting. The woman's auxiliary to the state association will hold its annual session at the Hotel President, April 23-24. Among the speakers will be Dr. William W. Bauer, Director, Bureau of Health Education, American Medical Association.

NEW JERSEY

The Medical Way.—The name of the official journal of the Medical Society of Cape May County is now the *Medical Way*. The name was chosen in a contest, the winners of which are James Murrin, newspaper editor of Franklin, Pa., and Dr. David B. Allman, Atlantic City, both of whom submitted the name. Both were awarded \$25 war bonds.

Study of Malarial Diseases.—The board of health of Elizabeth has undertaken a study of malaria infections in the city. A part of the educational program includes the dissemination of informative material to local physicians to assist in recognizing the disease and the furnishing to them of outfits for thick and thin blood smears for the laboratory diagnosis

of malaria. The Union County Mosquito Extermination Commission has again this year been granted an appropriation to be used for the prevention of anopheles breeding and to conduct research on *Anopheles quadrimaculatus*.

NEW YORK

Graduate Lectures.—A series of graduate lectures for the Madison County Medical Society, Oneida, opened on March 23 with a talk by Dr. A. Wilbur Duryee, New York, on "The Diagnosis and Treatment of Peripheral Vascular Disease." Others in the series include:

- Richard C. Arnold, Surgeon, U. S. Public Health Service, Early Observations on the Use of Penicillin in the Treatment of Syphilis, March 30
- Dr. Edward A. Bullard, New York, The Diagnosis and Treatment of Pelvic Pain, April 6
- Dr. Albert D. Kaiser, Rochester, Rheumatic Fever—Rheumatic Heart Disease in Children, April 13
- Dr. Harry Gold, New York, Management of the Failing Heart, April 20
- Dr. Harold D. Harvey, New York, Problems of Gastric Cancer, April 27

Cancer Teaching Day.—April 30 has been designated "Cancer Teaching Day" at Ellis Hospital, Schenectady. Among the speakers will be:

- Dr. William H. Woglom, New York, Modern Trends in Cancer Research
- Dr. Arthur Purdy Stout, New York, Tumors of the Peripheral Nerves and the Adipose Tissues
- Dr. Tordyce B. St. John, New York, Carcinoma of the Stomach—Results of Studies in a Surgical Clinic. The Responsibility of the General Practitioner and the Surgeon
- Dr. Hayes Martin, New York, Tumors of the Major Salivary Glands

The program will be presented under the auspices of the Medical Society of the County of Schenectady, the state medical society and the division of cancer control of the state department of health.

New York City

Appointments at Columbia.—The following new appointments to the staff of Columbia University College of Physicians and Surgeons have been announced:

- Samuel Gelfan, Ph.D., assistant professor of physiology
- Dr. Wendell L. Hughes, associate clinical professor of ophthalmology
- Dr. Willis S. Knighton, associate clinical professor of ophthalmology
- Dr. Edgar M. Medlar, associate professor of pathology
- Dr. Maxwell D. Ryan, associate clinical professor of otolaryngology

Alumni Day.—On April 29 "Alumni Day" will be observed at Long Island College of Medicine, Brooklyn. Speakers will include Drs. Emanuel Mendelson, on "Roentgenological Diagnosis of Intraperitoneal Fluid," A. L. Loomis Bell, "Chronic Intermittent Intussusception," and Phillips F. Greene, "China's Attack on Disease." At the annual dinner Mr. E. E. Conroy, U. S. Federal Bureau of Investigation, will discuss "The F. B. I. in Time of War."

Dr. Beeler Named Hospital Administrator.—Dr. James Moss Beeler, formerly medical superintendent of the Grady Hospital and assistant professor of psychiatry, Emory University School of Medicine, Atlanta, Ga., has been appointed hospital administrator of the Flower and Fifth Avenue Hospitals. A graduate of the University of Louisville School of Medicine in 1917, Dr. Beeler's most recent position was director of the department of mental hygiene of the Mississippi State Hospital, Whitfield.

Gifts Honor Memory of Physician.—Mrs. John Eastman Wilson has recently given a sum of money to New York Medical College Flower and Fifth Avenue Hospitals in honor of her late husband, who at one time was professor of diseases of the nervous system at the medical school and had been associated with the college from 1902 to 1918. Dr. Eastman died Dec. 19, 1929. One gift of \$100,000 has been designated as a student loan fund for needy medical students, and the other of \$10,000 has been added to the department of surgery.

Dr. Erdmann Observes Eightieth Birthday.—Dr. John F. Erdmann for many years director and professor of surgery, New York Post-Graduate Medical School and Hospital, Columbia University, observed his eightieth birthday March 27. He was guest at a tea given in his honor by the nurses at the hospital. Dr. Erdmann retired from his teaching position at New York Post-Graduate Medical School in 1934. He is consulting surgeon on the staffs of a number of hospitals. He was born in Cincinnati on March 27, 1864 and graduated at the Bellevue Hospital Medical College in 1887.

Million Dollar Gift to United Hospital Fund.—The Jacob H. and Emma W. Schoonmaker Fund has been created under a gift of one million dollars to the United Hospital Fund of New York from a trust created in 1937 by the late Jacob H. Schoonmaker, New York. The income of the fund is to be added to the annual collection made by the fund and distributed among the eighty-seven hospitals and homes par-

icipating. The remainder of the original trust is divided equally among the Community Service Society of New York, the New York Foundling Hospital, Fordham University and the Kingston Hospital, Kingston.

Dr. Marvin Thompson Chosen President of Warner Company.—Marvin R. Thompson, Ph.D., director of the Warner Institute for Therapeutic Research and vice president of the William R. Warner and Company, Inc., of New York and St. Louis, manufacturers of pharmaceutical products, has been chosen president of the company. Dr. Thompson once served as pharmacologist and later consultant pharmacologist to the U. S. Food and Drug Administration, associate professor of pharmacology, George Washington University School of Medicine, Washington, D. C., and professor of pharmacology and therapeutics, School of Pharmacy, University of Maryland, College Park.

Grant for Research in Industrial Medicine.—The New York Medical College has received a grant of \$30,000 from the Anaconda Wire and Cable Company for research projects in industrial medicine arising out of problems incident to the manufacture of the company's products. The study will determine whether occupational hazards exist and will develop means of giving adequate protection to the workers if necessary. The project is under the direction of Dr. Lindsley F. Cochen, director of the department of public health and industrial medicine, assisted by Dr. Linn J. Boyd, director of the department of medicine, and Dr. Francis D. Spear, director of the clinical pathology laboratories.

Master Plan for Hospitals and Related Facilities.—The planning committee of the Hospital Council of Greater New York plans to undertake this year the preparation of a master plan for hospitals and related facilities, the New York Times reported March 26. Dr. Haven Emerson has been named chairman of the committee to advise the council on the project, and other members include Dr. Jacob J. Golub, vice chairman; Dr. Edward M. Bernecker, commissioner of hospitals, Rev. John J. Bingham, Edward H. L. Corwin, Ph.D., David H. McAlpin Pyle and Edwin A. Salmon, all of the planning committee, and Neva R. Deardorff, Ph.D., Dr. Willis G. Nealley, Brooklyn, and Arthur W. Jones. The scope of the master plan, according to the Times, should show:

All existing hospitals and institutions for the care of the sick which shall have been determined to be satisfactorily located and provide adequate facilities and distribution of clinical services for the future communities to be served.

Those existing hospitals and institutions which are satisfactorily located but require minor changes and additions.

All proposed hospitals and institutions which shall be deemed to be desirable and which, in addition to existing facilities, shall make adequate provision for a comprehensive plan of hospitals, together with recommended locations of each, with sufficient detail of each facility to provide a complete understanding of the services to be contained therein.

Such hospitals as desire to be relocated, closed or merged with other hospitals.

OKLAHOMA

State Medical Meeting in Tulsa.—The fifty-second annual session of the Oklahoma State Medical Association will be held at the Mayo Hotel, Tulsa, April 24-26, under the presidency of Dr. James Stevenson, Tulsa. Among the guest speakers will be:

Dr. Walter C. Alvarez, Rochester, Minn., Nervous Breakdowns and Their Causes.

Dr. Duff S. Allen, St. Louis, Thyrotoxicosis in Older People.

Dr. Cecil K. Drinker, Boston, An Analysis of the Modern Treatment of Severe Burns.

Dr. Harry S. Mustard, New York, Implications of Tropical and Imported Diseases from a Public Health Standpoint.

Other speakers will include:

Major Welborn W. Sanger, M. R. C., Eye Conditions Among Military Men.

Lieut. Col. Earl Rankin Denny, M. C., A. U. S., Some Observations of the Clinical Use of Penicillin.

Lieut. Col. James C. Cain, M. R. C., Peptic Ulcer and Related Conditions.

William E. Graham, P. A. Surg., U. S. Public Health Service, The Significance of Abnormal Spinal Fluid Findings in the Diagnosis and Treatment of Neurosyphilis.

Major Silas H. Starr, M. C., A. U. S., The Present Status of Pain Relief During Labor.

Major Tom Wiley Hodges, M. R. C., Lessons Learned from the Use of the Roger-Anderson Apparatus.

Major William F. Hoyt, M. C., A. U. S., Care of Chest Injuries.

At the president's inaugural dinner dance Tuesday evening Dr. Alfred W. Adson, Rochester, Minn., member of the Council on Medical Service and Public Relations, American Medical Association, will discuss "The Federal Challenge to Practitioners of Medicine." Another feature of the session will be the annual spring meeting of the Oklahoma University Medical School Association. Classes to be honored this year are those of 1914, 1924, 1934 and 1944. Special tribute will be paid to Drs. Robert M. Howard and Everett S. Lain, professors

emeritus of surgery and dermatology and syphilology, respectively, University of Oklahoma School of Medicine, Oklahoma City. The woman's auxiliary to the state association will also convene.

RHODE ISLAND

"Family Physician" Honored.—The East Greenwich Lions Club and friends of Dr. Fenwick G. Taggart gathered at a reception in his honor February 28 in recognition of his forty years' service to the community. In an address as the speaker of the evening Dr. Arthur H. Ruggles, superintendent of the Butler Hospital, Providence, referred to Dr. Taggart as the "old type family physician." Dr. Taggart was presented with a silver bowl and candle sticks as a memento of the occasion. A public tribute was printed in the *Rhode Island Pendulum*, March 2, signed by George R. Hanaford, president of the town council. Dr. Taggart graduated at the University of Vermont College of Medicine, Burlington, in 1903.

SOUTH CAROLINA

Resolution Honors Work of State Health Officer.—The house of representatives on March 9 adopted a resolution commending the work of Dr. James A. Hayne, Columbia, for more than thirty-two years health officer of South Carolina.

TENNESSEE

Dr. Hardison Joins Red Cross.—Dr. Alonzo E. Hardison, director of the division of venereal disease control, Memphis and Shelby County Board of Health, recently resigned to become regional medical director for the American Red Cross, with headquarters in Atlanta, Ga.

VIRGINIA

University News.—Dr. Karl A. Menninger, Topeka, Kan., discussed "Psychiatry in Medicine" at the University of Virginia Department of Medicine, Charlottesville, recently under the auspices of the Phi Beta Pi medical fraternity. The annual Sigma Xi lecture was delivered February 9 by Kenneth C. D. Hickman, Ph.D., research chemist of the Eastman Kodak Company, Rochester, N. Y., on "Low Pressure Distillation and Vitamin Production." Dr. Theodore L. Squier, associate clinical professor of medicine, Marquette University School of Medicine, Milwaukee, addressed the Alpha Chapter of Alpha Omega Alpha, at the school, Charlottesville, February 18, on "Hematologic Manifestations of Hypersensitive States." The University of Virginia Medical Society was addressed February 28 by Dr. Everett I. Evans, Richmond, on "The Mechanisms and Management of Traumatic Shock." Dr. Samuel A. Vest Jr., Charlottesville, was elected president and Dr. Carlton J. Casey, Charlottesville, secretary.

GENERAL

Roentgenologists Plan Joint Session.—The Radiological Society of North America and the American Roentgen Ray Society will meet in joint session at the Palmer House, Chicago, September 24-29.

War Conference of Hospital Association.—The third war conference and the forty-sixth annual meeting of the American Hospital Association will be held at the Statler Hotel, Cleveland, October 2-6.

Pediatric Examinations.—The American Board of Pediatrics will hold a written examination for all applicants taking oral examinations September 22. The examination will be conducted by a monitor. Oral examinations will be held in St. Louis November 8-9 and in New York December 9-10. Additional information may be obtained from Dr. C. Anderson Aldrich, 115½ First Avenue S.W., Rochester, Minn.

Fund for Research in Allergy.—The recent establishment of a research foundation by the American College of Allergists has been announced. The foundation started with individual contributions of \$50 by a certain group of fellows in the college. Voluntary donations from members are acceptable. The college also announced the first annual gift of \$500 to the college from Marcelle Cosmetics, Chicago, to comprise the Marcelle Research Fund. The grant shall continue for a period of five years, and the money is to be used for such research in the field of allergy as the administrators of the fund may deem to be worthy of support.

Winners in National Traffic Safety Contest.—Utah and Aberdeen, S. D., are announced as the grand prize winners in the National Traffic Safety Contest conducted annually by the National Safety Council. All 48 states and 1,297 cities participated in the contest, which covered the calendar year 1943.

The contest rules provide that the national grand awards shall go to the state and city which, in the opinion of the judges, came nearest to doing the most that could be done practically for traffic safety. For five years, beginning in 1939, Aberdeen has not had a single traffic fatality. It has won four first places and one second in its population group, this year winning the grand prize, which for the first time has gone to a city with less than 50,000 population.

Noise Abatement Awards.—The National Noise Abatement Council will make four awards for civic achievement in noise abatement during 1944. An award will be given to the city in each of four population groups which presents the most conclusive evidence of outstanding accomplishment in the elimination of needless street noise and the control of industrial, office and in-the-home noises during the period June 6, 1943 to May 31, 1944 and in the observance of National Noise Abatement Week, April 30 to May 6, 1944. Material submitted as supporting evidence to claims for the awards must be received by the National Noise Abatement Council, 9 Rockefeller Plaza, New York 20, not later than July 1 and may consist of any or all of the following:

Newspaper clippings of news stories, photos, cartoons, features, editorials.

Photographs of civic and special activities, window and store displays.

Scripts of radio announcements and programs, other talks and lectures.

Official statements: photostatic or other copies of proclamations and statements issued.

Posters—car cards: samples or photos with number and method of distribution.

Record of events: dates, names and places—where and when events occurred.

Statement of results: official comment, safety and traffic records, other testimonials.

Any other material or evidence of a supporting nature.

Annual Report of Rockefeller Foundation.—A total of \$7,760,186 was appropriated by the Rockefeller Foundation in 1943 to cover its activities in six major fields; \$2,450,000 was earmarked for public health and \$1,529,000 for the medical sciences. According to the annual report of the foundation, other allocations included \$599,000 for the natural sciences, \$1,068,000 for the social sciences, \$1,055,000 for the humanities, and \$108,000 for the program in China.

The report discusses the progress made in the research in penicillin, crediting the work of Howard W. Florey, Ph.D., professor of pathology, Oxford University, and his associates for pioneering its clinical use.

In 1943 the laboratory at Lagos, West Africa, which had been opened in 1925 for the study of epidemiology of yellow fever and abandoned in 1934 because it was felt that its work could be carried on more effectively at other centers, was reopened to serve as a center for distributing yellow fever vaccine to troops and settlements in West Africa and to constitute a consultative service to the authorities in the British colonies of Gambia, Sierra Leone, the Gold Coast and Nigeria, where yellow fever has long been endemic. One of the main objectives of the new program centering in Lagos is to learn whether the jungle variety of mosquito discovered in South America has its counterpart in West Africa. If this proves to be the case, studies will be made there of the mechanism by which this form of yellow fever is transmitted to man, the work to be tied in with similar research now going forward in South America. The report states that the return to Lagos has a certain symbolic interest for the foundation, for it was in West Africa in 1927 that a blood specimen was taken from a black native named Asibi, who was sick with yellow fever. This specimen was inoculated into a rhesus monkey which had just been received from India. Asibi recovered, but the monkey died of the disease. All the vaccine manufactured since 1937, both by the Rockefeller Foundation and by government and other agencies as well, derives from the original strain of virus obtained from this humble native.

In its work on typhus the foundation, which had been concerned with the body louse as the principal carrier, sent, with the approval of the army, a typhus team to Algeria. Two extensive demonstrations there of louse control resulted in a new technic now being developed by which the insecticide is applied to individuals in a way which speeds up the process and makes possible the mass treatment of communities. The foundation is still carrying on its laboratory work on various strains of typhus in the hope of developing an effective vaccine.

In 1943, 107 men and women of Latin American countries studied on fellowships provided by the Rockefeller Foundation. Some of the appointees continued from 1942; 46 were new fellows who began their studies in 1943. A comparison of the 1943 program with that of twenty years ago, the report points out, finds public health and medicine still the dominant interests but no longer occupying the entire stage. Of the

107 fellowships active this year, 53 were in public health, 25 in medicine, 18 in the natural sciences and 11 in the humanities. Reviewing the fellowship appointments since they were created in 1917, it is found that the field of public health has claimed 328 Latin American fellows, medicine 112, the natural sciences 22, the humanities 32 and the social sciences 7—a total of 501. The fellows have come from nineteen countries, their fellowships representing a total expenditure of \$1,345,842.

The report states that Dr. Bernardo A. Houssay, professor of physiology, University of Buenos Aires, who, with others, was dismissed from his post for signing a petition to the government asking for "effective democracy and American solidarity," is continuing his research in a small laboratory established for him by an Argentine foundation. The Rockefeller Foundation has made a grant for equipment and supplies and for stipends to a number of scientists who wish to work with him.

The foundation declined 920 applications for financial aid in 1943 as compared with 1,121 in 1942. Some of the applications represented projects of interest which were rejected because other opportunities seemed more promising.

According to the report, Dr. Charles N. Leach, of the Far Eastern field staff of the International Health Division, and Mr. C. G. Copley, of the foundation's Manila office, returned to America on the exchange ship *Gripsholm* in December 1943. Both had been interned since the fall of Manila. At that time the Japanese looted the foundation's office and destroyed all records. In China, Dr. Henry S. Houghton, director of the Peiping Union Medical College, and Mr. Trevor Bowen, its comptroller, are still imprisoned, and hope for their early return seems slight. The buildings of the college have been taken over by the military and the greater part of their contents removed.

CANADA

Gift to Study Industrial Diseases.—The University of Western Ontario, London, Ont., has received \$100,000 from Mrs. William M. Gartshore, widow of the former president of the McClary Manufacturing Company, to "further the knowledge of disease caused by the conditions and hazards incidental to industry, so that such conditions may be improved and such hazards may be removed."

Canadian Medical Association Meeting.—The seventy-fifth annual meeting of the Canadian Medical Association will be held at the Royal York Hotel, Toronto, May 22-26, under the presidency of Dr. D. Sclater Lewis, Montreal, Que. The preliminary program mentions a series of round table conferences and section meetings on the specialties. General sessions will be addressed, among others, by Drs. Nicholson J. Eastman, Baltimore, on "The Management of Preeclampsia"; Russell B. Robson, Windsor, Ont., "Medical Care of the Industrial Worker," and Roy D. McClure, Detroit, "The Management of Breast Tumors."

FOREIGN

Deaths from Influenza Decrease Fifty Per Cent in Fortnight.—A recent report indicates that during the last week of December 1943 influenza mortality continued the decline begun earlier in the month in the large cities of England and Wales. It was stated that 464 deaths were attributed to the disease, against 1,109 and 690 during the two preceding weeks, accounting for a decline of 58 per cent in a fortnight.

Proposed Center for Treatment of Eye Diseases.—It is planned to establish at Oxford University a center for research and postgraduate study for the prevention of blindness and the better treatment of diseases of the eye. The Ophthalmological Research Endowment Committee plans to raise £250,000 for the purpose. *Science*, March 17, reports that about £26,000 toward the founding of a department of ophthalmology has been collected.

CORRECTION

Amputation with Refrigeration Anesthesia.—An abstract under this heading published in *THE JOURNAL*, March 18, page 808, read in part as follows: "The mortality for such amputations was formerly as high as 65 per cent. The ice and ligation method reduced this to 15.5 per cent in 45 patients who underwent 62 operations. The mortality for thigh amputations in this series was 13.3 per cent." These figures referred not to the author's series but to those of the City Hospital of New York as quoted by the author. The figures should have read "In our series the mortality was 28.5 per cent. A few years ago in the same two hospitals our mortality over a ten year period for all diabetic amputations was 75 per cent."

Foreign Letters

LONDON

(From Our Regular Correspondent)

March 11, 1944.

The Hospitals and the National Health Service

The proposed national health service regulates every field of medical practice, including every form of institutional care—not only all general and special hospitals but also sanatoriums for tuberculosis, accommodations for the chronically sick and infirm, for rehabilitation, for infectious diseases and for mental disorders. An important problem is the planning of collaboration between voluntary and municipal hospitals. At present these are independent and have originated in different ways. The beginning of the voluntary hospitals can be traced to the houses for the leprosy a thousand years ago and to the charitable movement begun by Pope Innocent III in the twelfth century and typified by the foundation in London of St. Bartholomew's Hospital in 1123. In modern times the voluntary hospitals have been founded and supported by voluntary subscriptions and donations. Thus the famous institution known as Guy's Hospital was founded by a bookseller named Guy, who endowed it with his fortune. All the British medical schools are attached to voluntary hospitals, and the advances of British medicine have mainly been the result of work performed in them.

The municipal hospitals have a different and much later origin. They originated in infirmaries for the chronically sick and infirm, established by law. Under the Local Government Act of 1929 many of these were converted into modern hospitals, with staff and apparatus which can rival the best voluntary hospitals. But they do not have the prestige of the voluntary hospitals. No medical schools are attached to them, and they have not yet had time to make medical history, though some excellent work has emanated from them. The need for cooperation between the two sets of hospitals under the unifying force of the national health service is obvious. Detailed surveys directed by the Ministry of Health are now proceeding. From these will come plans for the various areas. No voluntary hospital will be compelled to participate in the scheme for its area, but hospitals doing so will have to observe certain conditions which have been laid down. A new suggestion is that expert regional panels should be used for advice on the appointment of senior medical staffs. Hospitals agreeing to take part will receive payment for services rendered, and teaching hospitals may receive special financial assistance. But voluntary hospitals will still have to rely in part on the support of the public.

Exclusion of Women Students from Medical Schools

The right of women to enter the medical profession was won only after a long struggle, but complete equality with men has not yet been attained. In London there are twelve medical schools; one school admits only women students, two take a small proportion of women and the remaining nine have expressed inability to take women. In a letter to the *Times*, Sir Ernest Graham-Little, dermatologist and member of Parliament, points out that this denial of equal opportunities for the medical education of women conflicts with the recognized policy and tradition of London University, of which the medical schools are constituents. London is the pioneer university in admitting women to higher education, and this denial has caused grave disquiet in the university senate, of which Graham-Little is a member. In 1928 in conjunction with a well known surgeon, the late Mr. Walter Spencer, he brought forward a motion for an inquiry on the subject. A committee

was appointed and decided in favor of coeducation but did not recommend any drastic change. They recognized that there were economic difficulties which had largely governed the rejection of women students by the majority of London medical schools.

The war has produced an increasing demand for women doctors, and this again brings up the subject of greater facilities for the medical education of women. Graham-Little brought it before Parliament recently, but the minister of health declared himself unable to press acceptance of women on medical schools. He pointed out that the matter would engage the attention of an interdepartmental committee on medical education which he had set up. The senate of London University appointed a highly authoritative committee to report on the desirability of providing facilities for the medical education of women. Six of the seven members of the committee recommended the opening of all London medical schools to women on terms of equality with men. By an overwhelming majority the senate approved this. The *Times* states that as a result all the nine schools which now exclude women will probably admit them. But because of the complexity of the arrangements which will have to be made, the committee's recommendation is not likely to come into full effect until some years after the war. For one thing a considerable extension of buildings will be necessary to avoid providing women's facilities at the expense of the men. This might impede the flow of new doctors, which is of great national importance.

Extension of the Roehampton Artificial Limb Center

An extension of the Roehampton Limb Fitting Center was recently opened by the Chinese ambassador, Dr. Wellington Koo, who described the hospital as a fascinating and inspiring story of successful endeavor in a practically new field of service to humanity. It had restored to the injured, through the emphasis on their status as useful members of the community, that sense of dignity and self respect without which life became a burden, he stated. The new addition would be of special interest to the United Nations, he pointed out, as it made available to them the splendid facilities of the institution for making and fitting artificial limbs. The ambassador recognized that it was a gracious gesture for Great Britain to share with the Allies the knowledge, skill and experience acquired in thirty years of limb fitting.

Penicillin Research

Since the discovery of penicillin, Lord Nuffield, the automobile magnate who is well known for his gifts to medicine, has been interested in its antibacterial properties for the cure of disease. At his suggestion the Nuffield Provincial Hospitals Trust early in 1943 undertook to make grants of \$11,500 per annum for a period of five years toward the remuneration of the team of researchers working under Professor Florey at Oxford. The University of Oxford accepted these grants. This action has been taken by the trust with the concurrence of the Medical Research Council, which has been supporting the work for several years and is continuing to make a substantial grant for research expenses. Subsequently the trust also agreed to make substantial grants to enable the penicillin treatment of meningitis, abscess of the brain and other pyogenic diseases.

The Royal Commission on Population

The names of the members of the Royal Commission on Population and of its technical committees on the statistical, economic and biologic aspects of the population problem have recently been published. The statistical committee comprises well known writers such as A. M. Carr Saunders, D. V. Glass and R. R. Kuczynski. The last named member is distinguished for the introduction of "Kuczynski's unit," which isolates the factor on which the trend of population depends; it is called the "net reproduction rate." This expresses the number of

women in the next generation who will replace the women of reproductive age of this generation, if birth and death rates remain the same. If the net reproduction rate is unity, the population is exactly reproducing itself; if it is less, the population must diminish. Our reproductive rate in 1933 has been calculated at 0.734, less than three fourths of the rate necessary to sustain the present population.

BUENOS AIRES

(From Our Regular Correspondent)

March 4, 1944.

Endocrine Therapy in Cancer of the Breast

Dr. Erico Fels of Buenos Aires administered testosterone propionate to 3 patients with cancer of the breast. In none of the cases was the cancer cured. However, all the patients greatly improved. The degree of improvement depended on how soon in the course of the disease the treatment was administered. One patient had a uterine fibroma which disappeared in the course of the therapy. The second patient resorted to the therapy late in course of the disease. The improvement was moderate. The third patient had a cancer in the form of a cuirass. She is still under treatment. The progress of the big ulcer stopped after treatment was undertaken; the amount of fetid secretion diminished. In the microscopic preparations of the first case, after administration of testosterone propionate, a great proliferation of fibrous tissue was encountered, which was abundant in comparison to that observed in the biopsy taken before administration of the therapy. The fibrous tissue surrounded the focus of cancer. The tumor cells did not show any injury. Fels believes that testosterone propionate stimulates an acute proliferation of fibrous tissue which blocks the tumor cells and prevents their progress to the neighboring tissues. A direct effect on the substance of the tumor itself has not been proved as yet. The author advises further observations to verify the good results of this treatment.

Microflora of Meconium

Drs. Carlos P. Montagna and Maria S. Cataldi of the National Institute of Nutrition have reported their observations of 44 samples of meconium. The newborn infants were normal. Thirty-five were born in normal delivery, whereas 9 were delivered by cesarean section. The age varied from 5 minutes to 96 hours. Bacteria were present in all the samples of meconium; the amount increased with the age of the infant. The meconium contained enterococci in 93 per cent of the cases, colibacilli in 63 per cent, lipolytic bacteria in 50 per cent, bacteria which slowly fermented lactose in 47 per cent, proteolytic bacteria in 34 per cent, sporulated and nonsporulated anaerobes in 34 and 11 per cent respectively, fungi in 18 per cent and yeasts in 9 per cent of the cases. *Lactobacillus bifidus* was found in the meconium of 45 newborn infants. It was encountered twenty-four hours after birth in the group of normal deliveries and after forty-eight hours in the group of infants from cesarean sections. It was encountered in all cases before the infant received food. The authors concluded that the microscopic flora of the meconium is the same in groups of infants from normal deliveries and from cesarean section.

Public Health in Chile

The services of public health in Chile are distributed through three channels: the Department of Social Aid and Beneficence, the National Department of Public Hygiene and Sanitation and the Department of Social Work. The Department of Beneficence provides medical care, drugs and social aid to the poor. It supports and controls the national asylums and hospitals. The National Department of Public Health and Sanitation is concerned with the sanitation of the country, the prevention and control of epidemics and contagious disease, the organization

and maintenance of national sanitary personnel and the care of international health. It is concerned with various aspects of the protection of the individual, the family, the mother and her child. The centers of social insurance provide protection for the health of workers, civil employees of the state and members of the various armed forces up to a total number of 1,500,000.

One of the most important social insurance organizations is the Caja de Seguro Obligatorio de Enfermedad e Invalidez, which was founded in 1825. This organization provides insured workers and their wives and children up to the age of 2 years with medical care and medicines for therapeutic and preventive purposes. The organization also provides maternity care to the workers' wives, pensions to the family during illness of the wage earner and periods of rest to patients and nursing mothers. The monthly pension is equivalent to the whole monthly salary of the insured. Disability of the insured is compensated with a life pension. A retirement pension becomes effective at ages varying from 55 to 65 according to the age at which the insurance started. From 1925 to 1931 the insured was permitted to choose his physician. Later on, consulting offices were established in various zones of the country. The insured receive proper attention in the consulting offices, which are staffed by groups of appointed physicians. The consulting offices have equipment and facilities for giving general and specialized care and medicines to the insured. The organization also has its own pharmacies and dental and other laboratories. A movement to extend the benefits of social insurance to people living in rural areas was started recently.

Puerperal Inversion of Uterus

Dr. Victorio Monteverde, professor of gynecology of the Faculty of Medicine of the University of La Plata and dean of the faculty and head of the Center of Maternity and Social Assistance of the Hospital Piñero of Buenos Aires, with the collaboration of Dr. Diego Taylor Gorostiago recently published an article on the case of a multiparous woman with complete inversion of the uterus due to traction of the retained membranes after delivery. There was no shock. The inverted structure was introduced in the vagina. An operation was performed two days later. It consisted in exteriorization of the uterus, opening of the posterior aspect of the uterus, beginning at the neck and following it in an extension of 5 centimeters, and reinversion of the uterus. Because of the friability of the uterus, the lips of the surgical wound were only put in contact and peritonized, without suturing. The structure was powdered with azosulfamide and replaced after suturing of a 3 centimeter laceration on the anterior aspect, which occurred during the operation. A drainage tube was left in the Douglas cul-de-sac for forty-eight hours. A transfusion of total blood was administered. The postoperative period was normal. A small embolism occurred nine days later, after which the patient recovered fully.

Marriages

JERMAN WALTER ROSE JR., Henderson, N. C., to DR. GRACE MARIE COMARATTA of Harrisburg, Pa., in Pensacola, Fla., February 9.

NORMAN R. GOLDSMITH, Bethesda, Md., to Miss Emphila Fisher of North Judson, Ind., in Washington, D. C., March 24.

JOHN K. CHORLOG, Madison, Wis., to Mrs. Lydia F. McIntyre of Grand Forks, N. D., in Minneapolis, February 14.

STANLEY C. CLADER, Washington, D. C., to Miss Sue Ross Welch in New Orleans, March 11.

ORREN BOND LANDRUM to DR. LYDIA VIOLA WATSON, both of Dyersburg, Tenn., March 18.

JOHN M. CAMERON, Faunsdale, Ala., to Miss Harriet Connor of Peoria, Ill., March 11.

CARLE H. HOLMSTROM to Miss Estelle Filipi, both of Warren, Minn., March 16.

Deaths

Warren Taylor Vaughan * Richmond, Va., authority on allergy, died at his home, April 2, aged 51.

Dr. Vaughan was born in Ann Arbor, Mich., Feb. 22, 1893. He entered the University of Michigan Medical School, where he graduated in 1916. He served his internship at the Peter Bent Brigham Hospital, Boston. He was in the medical corps of the U. S. Army from 1917 to 1919, concluding his service with the rank of lieutenant colonel. While overseas he was chief of medical service at Camp Hospital 41, American Expeditionary Forces, Is-sur-tille, France. In 1920, ending a year as assistant in preventive medicine and hygiene at Harvard Medical School, Boston, Dr. Vaughan began the practice of medicine in Richmond, specializing in allergy. With Dr. W. Randolph Graham he founded the Vaughan-Graham clinic, known for its work in allergy diseases. It was in Richmond that Dr. Vaughan was instrumental in alleviating the allergy which affected Adm. William F. Halsey. A rash had incapacitated Admiral Halsey but Dr. Vaughan's treatment prepared him for his command in the Solomons in November, where he won a decisive victory against the Japanese.

Dr. Vaughan was the son of the late Dr. Victor C. Vaughan, once President of the American Medical Association and for many years closely allied with the association's activities. The late Dr. Victor C. Vaughan Jr. was his brother. Dr. J. Walter Vaughan, Richmond and Henry F. Vaughan, Dr.P.H., Ann Arbor, are also brothers. He leaves four sons, Warren T. Jr., Boston, and Victor C. 3d, New Haven, Conn., both of whom are physicians, and John H. and David Vaughan, students at Harvard Medical School.

Dr. Vaughan was a member of numerous organizations, including the Southern Medical Association, American Society of Clinical Pathologists, American Rheumatism Association, Society for Investigative Dermatology, International Society of Gastroenterology and the Virginia Academy of Science. He was an honorary member of the Institute of the Practice of Medicine, Barcelona, Spain, and the Society for the Study of Allergy, Argentina. He had been past president, vice president and secretary-treasurer of the American Association for the Study of Allergy and president of the Society for the Study of Asthma and Allied Conditions, and vice president of the Medical Society of Virginia, 1931-1932. He was a member of the committee on aerobiology of the National Research Council, director of the Research Council on Problems of Alcohol, and a fellow of the American Association for the Advancement of Science, serving since 1938 as a member of its council. He served on the advisory committee to the Committee on the Costs of Medical Care.

Certified as a specialist by the American Board of Internal Medicine, Dr. Vaughan's chief interest centered in the field of allergy. In addition to numerous articles on the subject, he was the author of "Influenza, an Epidemiologic Study," 1921; "Allergy and Applied Immunology," 1931 and 1934; "Practice of Allergy," 1939 and 1943; "Primer of Allergy," 1939, and "Strange Malady," 1941. He was editor of the *Journal of Laboratory and Clinical Medicine*, a position first held by his father, associate editor of the *Journal of Allergy*, member of the editorial board of the *American Journal of Digestive Diseases* and the *American Journal of Clinical Pathology*, and collaborating editor of *Folia clinica chimica et microscopica* (Bologna, Italy). He was once a member of the editorial board of the *Review of Gastroenterology* and of the *American Journal of Syphilis, Gonorrhea and Venereal Diseases*.

In 1941 the University of Michigan Medical School, Ann Arbor, where his father had served as dean for many years, awarded Dr. Vaughan the honorary degree of master of science for his "contributions to internal medicine and more particularly his notable studies in allergy."

Oswald Evans Denney * Senior Surgeon, U. S. Public Health Service, Galveston, Texas; University of Pennsylvania Department of Medicine, Philadelphia, 1913; resident physician at Philippine General Hospital, 1913-1914, and San Lazaro Hospital, Manila, 1914-1915; resident physician and later chief, Culion Leper Colony, Philippine Islands, from 1915 to 1919; executive officer of the fourth district, U. S. Public Health Service, 1919-1920; medical officer in charge of the National Leprosarium, Carville, La., from 1921 to 1935; chief quarantine officer of the Panama Canal Zone from 1936 to 1939; traveling representative for the Pan American Sanitary Bureau in 1940; fellow of the American College of Physicians; member of the American Society of Tropical Medicine, Association of Military Surgeons of the United States and the International Leprosy Association; since 1940 medical officer

in charge of the U. S. Marine Hospital and chief quarantine officer in Galveston; died February 19, aged 58, of pulmonary fibrosis due to old pulmonary disease.

Walter Bernard Coffey, San Francisco, died March 25, aged 75. He graduated from the Cooper Medical College, San Francisco, 1889. He was a member of the California Medical Association and at one time councilor of the Sixth District; also a fellow of the American College of Surgeons. Dr. Coffey was awarded the degree of doctor of laws from St. Mary's College, Oakland. He was a member of the staff and formerly president of St. Francis Hospital and served as chief surgeon of the Dollar Steamship Company and for many years as surgeon for the Southern Pacific Railroad and chief surgeon and general manager of the Southern Pacific Hospital. He was also said to be the first director of the Municipal Health Service System. In these positions he developed great influence and was for many years an important leader of medicine in California. In recent years his name had been associated with the promotion of the Coffey-Humber technic for treating cancer.

Curtis Campbell Mechling * Pittsburgh; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1903; specialist certified by the American Board of Surgery; member and past president of the American Proctologic Society; fellow of the American College of Surgeons; served as a captain in the medical corps of the U. S. Army during World War I; professor of proctology at the University of Pittsburgh School of Medicine and head of department of proctology at Falk Clinic; a member of the consulting staffs at Magee and Homestead (Pa.) hospitals; proctologist at Pittsburgh Diagnostic and Pittsburgh Skin and Cancer Clinics; senior staff proctologist at St. Francis Hospital and the Presbyterian Hospital, where he died March 1, aged 69, of heart disease.

Samuel Broders Moore, Alexandria, Va.; Georgetown University School of Medicine, Washington, D. C., 1897; member and formerly vice president of the Medical Society of Virginia; past president of the Alexandria City Medical Society and the Northern Virginia, District of Columbia and Maryland Medical Society; fellow of the American College of Surgeons; for many years surgeon for the Southern Railway System, Chesapeake and Ohio Railroad and the Richmond, Fredericksburg and Potomac Railroad as well as the Fruit Growers Express; served as chief surgeon, Alexandria Hospital; died March 15, aged 71, of coronary thrombosis with pulmonary edema.

Ernest Southerland Bulluck * Wilmington, N. C.; University of Maryland School of Medicine, Baltimore, 1911; past president of the New Hanover County Medical Society; formerly vice president of the Medical Society of the State of North Carolina; fellow of the American College of Surgeons; served in the medical corps of the U. S. Army during World War I; surgeon, Community Hospital; on the courtesy staff, James Walker Memorial Hospital; consulting surgeon, Wilmington Red Cross Sanatorium; founder and medical director, Bulluck Hospital, where he died March 13, aged 55, of coronary thrombosis.

Henry Robert Gledhill * Jerseyville, Ill.; College of Physicians and Surgeons, New York, 1894; past president of the Jersey County Medical Society; recently a member of the examining board of the Jersey County Selective Service; secretary of the county draft board during World War I; for many years a member of the board of education, serving two terms as president of the Jersey township high school; served on the board of directors of the Jerseyville Public Library and as a member of the George Washington Educational Fund; died February 12, aged 75, of cerebral hemorrhage.

William Parr Davidson * Decatur, Ill.; Louisville (Ky.) Medical College, 1897; past president of the Moultrie County Medical Society; first lieutenant in the medical officers reserve corps during World War I; chief surgeon, Illinois Masonic Home, Sullivan, from 1903 to 1914; local surgeon for the Illinois Central Railroad from 1910 to 1925 and the Chicago and Eastern Illinois Railroad from 1915 to 1923; on the staffs of the Decatur and Macon County Hospital and St. Mary's Hospital, where he died February 10, aged 72, of pulmonary edema, myocardial failure and coronary occlusion.

Marie K. Formad, Philadelphia; Woman's Medical College of Pennsylvania, Philadelphia, 1886; formerly clinical professor of gynecology at her alma mater; served with the women's overseas unit for fourteen months in France during World War I and was decorated by the French government; in 1936 the Marie K. Formad Endowment Fund was established at the Woman's Hospital, where she had been chief of the gynecologic staff and later a member of the consulting staff; died in the Friends Hospital February 21, aged 83, of coronary artery disease and arteriosclerosis.

Edgar Gordon Cuddeback * Port Jervis, N. Y.; Cornell University Medical College, New York, 1906; examining physician for the draft board; vice president and a director of the National Bank and Trust Company of Port Jervis, a director of the Port Jervis Savings and Loan Association and of the Port Jervis Hotel Corporation; a member of the executive committee of the Minisink Valley Historical Society; for many years surgeon for the Erie Railroad; on the staff of St. Francis Hospital, where he died February 10, aged 61, of congestive heart disease.

George W. Larendon, Kerrville, Texas; Jefferson Medical College of Philadelphia, 1889; member of the State Medical Association of Texas; formerly a major in the medical corps of the Texas National Guard; served during World War I; lieutenant colonel in the medical reserve corps of the U. S. Army, not on active duty; at one time health officer of the city of Houston and Harris County; served as deputy state health officer; formerly on the staffs of St. Joseph's Infirmary and the Memorial Hospital; died in Houston February 18, aged 75, of uremia.

Frank Clemm Adams * Yellow Springs, Ohio; Cincinnati College of Medicine and Surgery, 1901; past president of the Greene County Medical Society; died in the McClellan Hospital, Xenia, February 12, aged 79, of arteriosclerotic heart disease and diabetes mellitus.

William Pitt Baldwin * New Haven, Conn.; Yale University School of Medicine, New Haven, 1890; New York Homeopathic Medical College and Hospital, New York, 1891; fellow of the American College of Surgeons; at one time a member of the board of councilmen, an alderman, representing the first ward, and a member of the city park commission; consultant, Charlotte Hungerford Hospital, Torrington; consultant in surgery, Grace Hospital, where he died February 5, aged 76, of pneumonia.

Willard Asa Bates * Littleton, N. H.; Dartmouth Medical School, Hanover, 1901; served in the medical corps of the U. S. Army during World War I; on the staff of the Littleton Hospital; president of the Lions Club; died suddenly February 8, aged 66, of cerebral hemorrhage.

Gerrit Judd Bennett, Waterloo, Iowa; Kansas City (Mo.) Medical College, 1895; died February 6, aged 84, of a self-inflicted bullet wound.

Elbert Amsden Bing, Marshall, Ark.; St. Louis University School of Medicine, 1906; member of the Arkansas Medical Society; past president of the Searcy County Medical Society and the Ninth Councilor District Medical Society; died February 2, aged 67, of heart disease.

Frank Wheeler Braden * Washington, D. C.; Georgetown University School of Medicine, Washington, 1895; for many years examining physician and surgeon for the Standard Oil Company and police surgeon for the District of Columbia; served as examiner for the Panama Canal Commission; died February 19, aged 72, of ruptured aortic aneurysm.

Cerilda Niswonger Bromley, East St. Louis, Ill.; Woman's Medical College, Chicago, 1891; died February 4, aged 78, of acute dilatation of the heart, arteriosclerosis and chronic myocarditis.

Joseph Cecire, Newark, N. J.; Long Island College Hospital, Brooklyn, 1909; died February 3, aged 67, of coronary occlusion, hypertension and arteriosclerosis.

Cono Ciuffa * Chicago; Northwestern University Medical School, Chicago, 1927; formerly a Methodist minister; for many years clinical assistant in surgery at his alma mater; served as senior physician on the staff of the Cook County Infirmary, Oak Forest, Ill.; on the staffs of the Walther Memorial and Grant hospitals; member of the chamber of commerce of Park Ridge, Ill.; died suddenly February 11, aged 50, of cerebral hemorrhage.

Celia O. Clemans, Dover, Ohio; Homeopathic Hospital College, Cleveland, 1893; died in the Elyria Memorial Hospital, Elyria, February 13, aged 83, of generalized arteriosclerosis and hypertension.

Benjamin Myron Cohen, Cambridge, Mass.; Tufts College Medical School, Boston, 1927; died suddenly February 9, aged 41, of acute dilatation of the heart.

Hugh Francis Crawford * Memphis, Tenn.; Memphis Hospital Medical College, 1903; assistant professor of medicine at the University of Tennessee College of Medicine; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; member of the National Gastroenterological Association; served as attending physician, John Gaston, Baptist Memorial and Methodist hospitals; on the editorial board of the *Review of Gastroenterology*; died February 18, aged 61, of tuberculosis.

Edward Joseph Cronin, Boston; Tufts College Medical School, Boston, 1921; head of draft board number 37, Allston, Mass.; junior chief of medical staff and secretary of staff, St. Elizabeth's Hospital; died in the Cardinal O'Connell House of the hospital February 11, aged 46, of acute disseminated tuberculosis.

Volney Nevin Fackler * Richmond, Ind.; State College of Physicians and Surgeons, Indianapolis, 1907; died February 1, aged 71, of coronary occlusion.

Leslie Freudenthal * Gridley, Calif.; University of California Medical School, San Francisco, 1926; served during World War I; member of the Gridley Rotary Club; died in an Oroville hospital March 1, aged 44, of injuries received in an automobile accident.

Realious Farrow Goolsby, Chicago; Meharry Medical College, Nashville, Tenn., 1913; on the staff of the Provident Hospital; died February 3, aged 59, of carcinoma of the brain.

Solomon Greenbaum, Newark, N. J.; Bellevue Hospital Medical College, New York, 1889; for many years on the staff of the Beth Israel Hospital; died February 24, aged 85, of arteriosclerosis.

Delbert Davis Hamlin * Marlboro, Ohio; University of Louisville (Ky.) School of Medicine, 1932; on the staffs of the City Hospital, Alliance, and the Mercy Hospital, Canton; died February 17, aged 39, of cardiac occlusion.

Joseph Augustus C. Hartman * Eggertsville, N. Y.; University of Buffalo School of Medicine, 1920; died in the Millard Fillmore Hospital, Buffalo, recently, aged 46, of multiple neuritis and bulbar paralysis.

Jacob Abraham Hartmann * St. Louis; Washington University School of Medicine, St. Louis, 1896; served as autopsy physician to coroner city of St. Louis; served during World War I; died in St. Luke's Hospital February 3, aged 74, of common duct stones and perforation of bowel.

Frank T. Harvey, Milford, Mass.; New York Homeopathic Medical College and Hospital, New York, 1893; formerly physician in charge of the Harvey Hospital; honorary member of the staff of the Milford Hospital; died in the Worcester Hahnemann Hospital, Worcester, February 1, aged 77, of coronary thrombosis and pneumonia.

Charles Higby Hoffhine * Columbus, Ohio; Starling Medical College, Columbus, 1905; at one time instructor in ophthalmology at the Ohio State University College of Medicine; on the staff of the Grant Hospital, where he died February 8, aged 60, of heart disease.

Walter Chester Kite * Milton, Mass.; University of Pennsylvania Department of Medicine, Philadelphia, 1893; member of the New England Pediatric Society; served on the local board of health; for many years on the staffs of the Milton Hospital and Convalescent Home and the Boston Home for Incurables; died February 5, aged 79, of coronary thrombosis.

Louis Landman * New York; New York Homeopathic Medical College and Flower Hospital, New York, 1918; clinical assistant, department of surgery, New York Medical College, Flower and Fifth Avenue Hospitals; member of the staffs of the Misericordia and Metropolitan hospitals; died February 7, aged 54, of malignant hypertension.

Joseph Verner Leech * Pittsburgh; University of Pittsburgh School of Medicine, 1928; on the staff of the Columbia Hospital, Wilkensburg, where he died February 9, aged 47, of Hodgkin's disease.

John D. Lindsay, Spring City, Tenn.; Chattanooga Medical College, 1901; died in the Chamberlain Memorial Hospital, Rockwood, January 18, aged 67, of heart disease and pneumonia.

Cornelius D. Mackey, Chicago; University of Buffalo School of Medicine, 1889; member of the Illinois State Medical Society; died February 27, aged 83, of chronic myocarditis.

John Galbraith Mackey * San Fernando, Calif.; University of Southern California College of Medicine, Los Angeles, 1898; founder and owner of the San Fernando Hospital, where he died February 11, aged 72, of cerebral hemorrhage.

Charles Mackin MacNelly * Weatherford, Texas; University of Nashville (Tenn.) Medical Department, 1893; past president of the Palo Pinto-Parker Counties Medical Society; died February 5, aged 69, of coronary occlusion.

Charles Benton Marshall, Nitro, W. Va.; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1920; member of the West Virginia State Medical Association; formerly an assistant surgeon in the U. S. Public Health Service reserve; died in the University Hospital, Baltimore, February 5, aged 49, of cerebral hemorrhage.

Henry Allen May * Washington, Mo.; Beaumont Hospital Medical College, St. Louis, 1894; formerly secretary of the Franklin County Medical Society; on the staff of St. Francis Hospital; physician for the Missouri Pacific Railroad; died January 31, aged 71, of chronic myocarditis.

James A. McCollam, Uhrichsville, Ohio; Starling Medical College, Columbus, 1890; member of the Ohio State Medical Association; past president and secretary of the Tuscarawas County Medical Society; served as the first health commissioner of Uhrichsville and for three terms as president of the board of trade; founder and formerly head of the Uhrichsville high school library association; member of the chamber of commerce; died March 13, aged 75, of acute coronary occlusion.

Wyatt Young McDaniel * Taylors, S. C.; Chattanooga (Tenn.) Medical College, 1900; died January 21, aged 70, of arteriosclerosis and cerebral hemorrhage.

Guy Tingley Meek, Bexley, Ohio; Starling Medical College, Columbus, 1896; member of the Ohio State Medical Association; served as a captain in the medical corps of the U. S. Army during World War I; from 1919 to 1932 medical examiner for the U. S. Veterans Administration; on the staff of St. Francis Hospital, Columbus; died January 24, aged 69, of carcinoma of the right side of the kidney and liver.

D. Wesley Moore, Jellico, Tenn.; University of Louisville (Ky.) Medical Department, 1887; member of the Tennessee State Medical Association; formerly mayor of Jellico; died January 22, aged 83, of pneumonia.

John Thomas Mosser, Caneyville, Ky.; Hospital College of Medicine, Louisville, 1907; died January 27, aged 68, of pneumonia.

Charles Light Mulherin, Newbern, Tenn.; Vanderbilt University School of Medicine, Nashville, 1910; died in the U. S. Public Health Service Hospital, Lexington, Ky., January 23, aged 57, of carcinoma of the digestive tract.

Roscoe Damon Perley * Melrose, Mass.; Harvard Medical School, Boston, 1896; for many years on the staff of the Melrose Hospital; formerly on the staffs of the Massachusetts General and Boston Lying-in hospitals, Boston; died January 21, aged 80, of heart disease.

Urban Joseph Whitehead Peters * Birmingham, Ala.; University of Pennsylvania Department of Medicine, Philadelphia, 1898; member of the Rotary Club; on the staff of St. Vincent's Hospital, where he died January 26, aged 74, of myocardial failure.

John Lyte Ressler, Bird In Hand, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1899; member of the Medical Society of the State of Pennsylvania; served as deputy coroner for many years; at one time medical director of the Lancaster County Hospital and Hospital for Insane, Lancaster; died January 21, aged 74, of diabetes mellitus.

George Anthony Retel, Buffalo; University of Buffalo School of Medicine, 1893; member of the Medical Society of the State of New York; at one time school physician; died in the Deaconess Hospital January 21, aged 75, of pneumonia.

Felix Rose, Green Bay, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1900; physician at the Odd Fellows Home; died January 15, aged 66, of acute appendicitis and complications.

Myra Daniel Allen Ruppel, Pasadena, Calif.; Woman's Medical College of Pennsylvania, Philadelphia, 1887; for many years a member of the school committee in Lynn, Mass.; died in January, aged 81.

Purnell Fletcher Sappington, Perry Point, Md.; University of Maryland School of Medicine, Baltimore, 1887; member of the Medical and Chirurgical Faculty of Maryland; also a pharmacist; served during World War I; for many years chairman of the Bel Air town board; died in the Veterans Administration Facility January 23, aged 79, of coronary disease and arteriosclerosis.

Franklin Taylor Scanlon * Morgantown, W. Va.; University of Nashville (Tenn.) Medical Department, 1910; past president of the Monongalia County Medical Society and vice president of the West Virginia State Medical Association; captain in the medical corps of the U. S. Army during World War I; a director of the First National Bank and a member of the Kiwanis Club; on the staffs of the Heiskell Memorial Hospital and the Monongalia General Hospital, where he died February 25, aged 65, of mesenteric thrombosis.

Bert A. Smith, Auburn, Neb.; Chicago College of Medicine and Surgery, 1913; member of the Nebraska State Medical Association; on the staff of the Auburn Hospital; died January 11, aged 55, of coronary thrombosis.

Okey Warren Snodgrass, Frankford, Mo.; Barnes Medical College, St. Louis, 1910; died in St. Elizabeth's Hospital, Hannibal, January 28, aged 68, of heart disease.

Howard Somers, Morgan Hill, Calif.; Cooper Medical College, San Francisco, 1904; member of the California Medical Association; died in the Wheeler Hospital, Gilroy, January 20, aged 63, of heart disease.

John Wilson Stevenson, Hoquiam, Wash.; Drake University College of Medicine, Des Moines, 1907; member of the Washington State Medical Association; formerly county coroner and city health officer; died in Aberdeen January 20, aged 79, of cerebral hemorrhage.

Joseph Milton Trigg * St. Louis; College of Physicians and Surgeons, Keokuk, Iowa, 1893; at one time professor of clinical surgery and surgical pathology at the

St. Louis College of Physicians and Surgeons; on the surgical staff of the Missouri Baptist Hospital, where he died January 27, aged 73, of pneumonia.

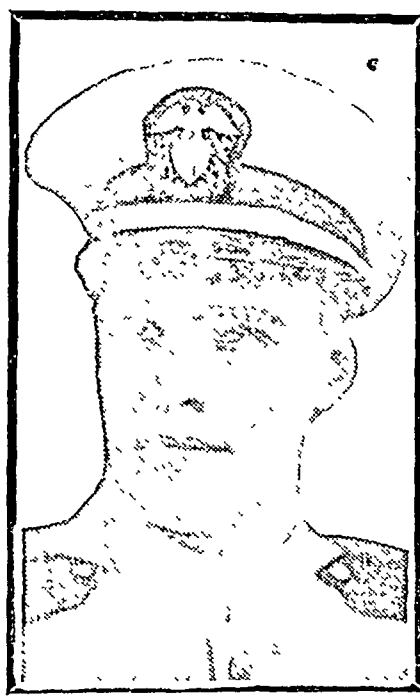

KILLED IN ACTION

Walter Spohn Caldwell * Kilgore, Texas; University of Texas School of Medicine, Galveston, 1931; formerly a member of the Kilgore Junior Chamber of Commerce and Lions Club; began extended active duty as a captain in the medical corps, Army of the United States, on Aug. 25, 1942; attached to an antiaircraft battalion; killed in action in the North African area, Nov. 20, 1943, aged 38.

Delbert Bevan Mallams, Ashland, Pa.; Temple University School of Medicine, Philadelphia, 1941; served internship at the Robert Packer Hospital, Sayre; commissioned a lieutenant (jg), medical corps, U. S. Naval Reserve, on July 14, 1942; began extended active duty Sept. 7, 1942 with the amphibious force, Paradise Creek Dispensary, Norfolk Navy Yard, Portsmouth, Va.; medical and surgical officer in charge of a flotilla of 18 LCI boats; participated in the invasions of Pantelleria, Sicily, Salerno, Nettuna and the battle of Anzio; recipient of five stars, European medal, Presidential Citation and the Purple Heart; promoted to lieutenant; drowned at sea while in naval action off the Anzio beachhead, January 26, aged 28.

CAPT. WALTER S. CALDWELL
M. C., A. U. S., 1905-1943

LIEUT. DELBERT B. MALLAMS
(MC), U.S.N.R., 1915-1944

Bureau of Investigation

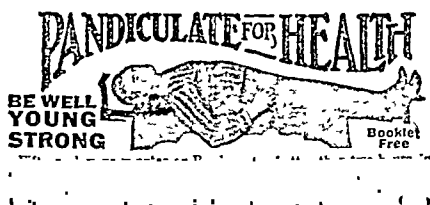

DAVID B. CROPP CROPS UP AGAIN

Post Office Department Detects Old Fraud Under New Name

For many years David B. Cropp of New York has been in and out of a fraudulent "height increasing" scheme perpetrated through the mails. It began apparently with "The Pandiculator," one of the earliest of the alleged spine-stretching devices. This one was advertised in pulp periodicals at least as far back as 1914.

Whether Cropp was its originator is not clear. In 1918 he sold the business to one Henry C. Crowell, a Cleveland attorney, according to the latter's testimony in 1941, when his concern, known as the Pandiculator Company, was debarred from the mails by the Post Office Department as a fraud. Some time after buying the thing from Cropp, Crowell, according to his testimony, sold it to a Harry L. Spaulding, from whom he bought it back in 1932 and operated it until 1941, when the aforementioned fraud order was issued against the names The Pandiculator Company and H. C. Crowell.

In April 1942 an additional fraud order was issued against H. C. Crowell alone, after the Post Office discovered that he had simply remained in the business and run it under his own name instead of that of the Pandiculator Company. Meantime, it appears, Cropp had reentered the business or started a competing one, operating under the trade style "International Health Device Corporation" and calling his product "The Therapeutic

A typical "Pandiculator" advertisement

Couch" or "The Cropp Therapeutic Couch." The description of it seems to correspond to that of the Pandiculator. Reportedly Cropp used testimonials from laymen, osteopaths, chiropractors and physiotherapists as to the efficacy of the couch in treating many serious disorders, besides increasing height and reducing weight and waistline measurements. This enterprise also came to grief when a Post Office fraud order was issued in October 1942 against the names David Cropp, David B. Cropp and the International Health Device Corporation.

But Cropp apparently decided not to let a mere government ukase interfere with his profits. He hit on a new trade style, "Physical Improvement, Inc.," but retained the old name for his mechanical fraud, "The Therapeutic Couch." Again the Post Office Department got on his trail and discovered that he was using as his chief advertising material a book, "The Human Body," which he had employed in promoting his earlier scheme. In this latest venture, according to evidence gathered by the government, Cropp's letters to prospective customers intimated that they were evidently practitioners of the healing arts, otherwise they would not be inquiring about his Couch, since he said he had for several months advertised it in professional journals. This, the Post Office declared, was a false representation, as shown by his simultaneous advertising in a cheap health periodical widely circulated among laymen as well as health-fad practitioners.

When Cropp was ordered by the Post Office Department to show cause why his Physical Improvement, Inc., should not be debarred from the mails on grounds of fraud, he presented as a witness in his behalf a naturopath licensed as such in Connecticut, Florida and the District of Columbia, and as a physiotherapist in New York state. After hearing all the evidence, the Post Office Department found that Physical Improvement, Inc., not only was a continuation of Cropp's previous fraud, and an attempt to evade the fraud order issued against Cropp and

the International Health Device Corporation, but was in itself a swindle. Accordingly, a new fraud order was issued on Aug. 7, 1943 against Cropp and his latest trade designation, Physical Improvement, Inc.

Note the finding of the Post Office Department that even before the fraud order against Cropp's International Health Device Corporation had been issued (although expected) Cropp had already incorporated his latest enterprise, Physical Improvement, Inc., thus showing his determination to continue the swindle, and that in this move he was assisted by a Jay H. Radley, M.D. The only person of this name in the American Medical Directory is listed under New York City. According to the data, he was born in 1863, was graduated from the old College of Physicians and Surgeons, Chicago, in 1889 and licensed to practice medicine in thirteen states. In 1929 one of the government departments at Washington, after looking into an advertised "obesity cure," reported that some of its promotional literature referred to Dr. J. H. Radley of New York as a recognized authority on skin diseases and featural defects. It has also been reported that J. H. Radley once authored an article in a chiropractic journal and that after his name were the letters "M.D., D.C.," the "D.C." presumably standing for "Doctor of Chiropractic."

The previous fraud orders issued against the various names under which this brazen scheme was perpetrated were dealt with at considerable length in this department of THE JOURNAL for April 4, 1942, page 1240; Dec. 12, 1942, page 1243, and Feb. 19, 1943, page 537. Apparently this swindle is hard to scotch. There seems to be something appealing in the idea that one may grow tall and strong and beautiful just by lying down on a special kind of couch! When will Cropp crop up again?

STIPULATIONS

Agreements Between Federal Trade Commission and Promoters of Various Products

Following are abstracts of stipulations in which promoters of "patent medicines," medical devices and cosmetics have agreed, following action by the Federal Trade Commission, to discontinue certain misrepresentations in their advertising. These stipulations differ from the "Cease and Desist Orders" of the Commission in that such orders definitely direct the discontinuance of misrepresentations. The abstracts that follow are presented primarily to illustrate the effects of the provisions of the Wheeler-Lea Amendment to the Federal Trade Commission Act on the promotion of such products:

Chu Suey Gee Chinese Medicines.—These are put out under the name of the Suey Chee Herb Company, San Francisco, which is a trade name for one Chu Suey Gee. In May 1943 he stipulated with the Federal Trade Commission that he would cease representing that his pills strengthen the heart or that their use is indicated for that purpose.

Needee Acidophilus Culture and Needee Lactone.—In May 1943 the Federal Trade Commission accepted a stipulation from John T. Heinrichson, trading as Heinrichson's Natural Food Company, Chicago. In this he agreed to discontinue any advertising which represented that either of his preparations is a cure or remedy or effective in the treatment of diarrhea, intestinal flatulence, rheumatism, arthritis, metabolic disorders, hyperacidity, colitis or arteriosclerosis, that either will drive out putrefactive bacterial or toxic poisons, that through the use of these youth, beauty or lasting health can be obtained, or that any Needee food product is guaranteed by or insured against imperfections by Lloyd's of London or any other insurer or guarantor.

Security Suppositories and Stillman's Suppositories.—In April 1943 the Chicago Mail Order Company, Chicago, entered into a stipulation with the Federal Trade Commission, to the effect that it would cease representing, by use of the designation "security" or by any other means, that its suppositories give security or complete protection against conception or are nonirritating to normal vaginal tissue.

Si-Oze.—This is put out by one Berdve H. Sigel, trading as the Si-Oze Company, Chicago. In May 1943 this person stipulated with the Federal Trade Commission to discontinue any advertising which failed to reveal that excessive use of this product may be dangerous or that it should not be administered to infants and younger children except on competent advice, or used by persons suffering from high blood pressure, heart disease, diabetes or thyroid trouble, and further, that frequent or continued use of this preparation may cause nervousness, restlessness or sleeplessness. The stipulation provided, however, that such advertising need contain only the statement, "Caution—Use only as directed" when the labeling contains a warning to the same effect.

FAILURE OF THE SWEAT MECHANISM IN THE DESERT

To the Editor:—I should like to comment briefly on the report in THE JOURNAL February 19 concerning the subject of "Failure of the Sweat Mechanism in the Desert" and "Thermogenic Anhidrosis."

In view of the great importance of this subject as regards both the armed forces and industry, reliable data concerning these functions is greatly needed. There is no doubt that prolonged exposure to heat, particularly when considerable physical activity is required, leads in the course of time, to serious salt depletion (NaCl) associated with symptoms, of serious muscular weakness, muscular and abdominal cramps, drowsiness, loss of appetite and such central disturbances as increased irritability, nausea, vomiting, vertigo, fever, visual disturbances and delirium, in some instances culminating in tetany and collapse.

Anhidrosis has been found to be most frequently associated with chloride deprivation and dehydration. Since the work of Bunge and others has shown that the largest part of the approximately 100 Gm. of sodium chloride contained in the average human body is to be found in the tissues (approximately 60 per cent or more), it is reasonable to assume that a considerable amount of chlorides can be lost without a corresponding lowering of the blood chloride level, which the organism attempts to maintain tenaciously.

The authors of the report apparently assume that the maintenance of the blood chloride level within normal limits in a majority of the cases which they have observed was sufficient evidence to justify the assumption that a sodium chloride deficiency did not exist (see comments by Peters, pages 299 and 300 of Duncan's "Diseases of Metabolism"). However, it is interesting to observe that in case 6, as reported, a satisfactory minimum replacement of the chloride loss (2,000 cc. of 5 per cent dextrose in isotonic solution of sodium chloride) had been given on admission, and that this was followed by a prompt remission of the clinical symptoms, with a return to normal sweat function within twenty-four hours. Further they point out that all of their patients were given some form of salt therapy, 4 to 6 Gm. daily as oral tablets, in addition to using drinking water containing 0.1 per cent solution of sodium chloride. This addition to their daily intake they noted failed to relieve the symptoms. Most authors agree that such patients should receive a minimum of 25 Gm. of sodium chloride added to their intake within the first twenty-four hours, preferably as isotonic solution intravenously in addition to the oral intake. Under desert conditions this would seem indeed a minimum requirement in order to facilitate recovery from severe chloride depletion.

The authors note further that following recovery of the sweating function the symptoms could not be provoked when the patient was temporarily subjected to excessive heat of the desert sun.

Here we must raise the question as to whether their salt depletion and dehydration had been partially or completely dissipated before they could stand such a test satisfactorily, especially in view of the return of the sweat function.

The authors' conclusion that salt is not indicated and of no therapeutic value is a dangerous assumption in view of the existing physiologic evidence to the contrary. Do their observations rest on sufficient experimental evidence to support such a conclusion?

MICHAEL M. MILLER, Ellis Island 4, N. Y.
Assistant Surgeon (R), U. S. Marine Hospital.

To the Editor:—In the article on "Failure of the Sweat Mechanism in the Desert" (THE JOURNAL February 19) by Wolkin, Goodman and Kelley a new syndrome is presented and an attempt is made to "demonstrate that the presence or absence of normal sweating function is the determining factor in the production of the syndrome."

In the article no mention is made of the cortical influence on general body sweating. It is a physiologic fact that during mental stress on a very hot day there is a suppression of general body sweating. (Kuno, Yas: The Physiology of Human Perspiration). The anxiety state, which is a stimulus for palmar sweating, may during extreme elevations of temperature inhibit both palmar and general body sweating. This paradoxical inhibition of sweating also occurs in severe heat strokes. It seems unreasonable to believe that this inhibition seen in heat stroke is caused by paralysis of the sweat glands, for there is a prompt restoration of sweating when the patient is placed in cool surroundings. The limitation of sweating to the face and neck is difficult to explain. The possibility of local reflex action to these exposed parts cannot be excluded.

A review of the symptoms in the 8 cases presented by the authors suggests a psychogenic factor: "shaky and weak" (case 1), "head whirling" (case 2), "all in feeling" (case 3), "light headed and extremely weak" (case 4), "light headed" (case 5), "dizzy while on the firing range" (case 6), "lost consciousness for a few seconds" (case 7), "burning up" (case 8).

It is noteworthy that all the patients improved when placed in a different environment. Obviously, if psychic influences were the basis for this improvement, it is understandable why there was no disturbance in the blood chlorides.

In summary it is felt that the syndrome described by the authors is fundamentally a psychosomatic phenomenon. The inhibition of sweating is secondary. Further investigations from a psychosomatic point of view are indicated.

JACOB J. SILVERMAN,
Captain, M. C., A. U. S.
VERNON E. POWELL,
Lieutenant Colonel, M. C., A. U. S.

ANHIDROSIS FOLLOWING EXPOSURE TO EXTREME HEAT

To the Editor:—In THE JOURNAL, February 19, Wolkin, Goodman and Kelley reported the interesting syndrome of anhidrosis following exposure to extreme heat. One case of this syndrome was studied in Louisiana during the summer of 1943. This man presented the identical picture which they describe: of uneventful previous exposure to heat with a sudden onset of weakness and malaise but no true heat or sun stroke following a particularly difficult march on a hot, humid day. On examination he showed dry skin of the extremities and trunk with pronounced sweating of only the face and neck, which they found characteristic. In the cool of the hospital he was quite comfortable unless he drank hot liquids, at which time flushing of the face associated with profuse sweating of the face and neck was reproduced. The same effect in the areas was produced by the injection of physostigmine. The findings were corroborated with Minor's starch-iodine technic.

The local skin changes are of great interest to the dermatologist and perhaps should be more strongly emphasized. In addition to the scaling, fine papular lesions which the authors describe, our patient later developed over the extensor surfaces of his arms and legs and on his trunk another distinct derma-

toxis. It consisted of superficial, more or less circinate areas of slight erythema with moderate white scaling and mild pruritus. The scaling was patchy and similar to ichthyosis but could be differentiated from congenital ichthyosis without difficulty. Two other diseases which may have a similar appearance are pityriasis rosea and tinea circinata. The coloring, distribution and course help differentiate it from the former, while the very superficial character and lack of fungi in the scales prove it different from the latter.

About 20 additional patients were seen in consultation for a skin disease which was identical in distribution, appearance, symptoms and course with that described. None of these patients, as far as could be determined, had had an episode of "thermal anhidrosis." All of them had spent the summer in Louisiana, however, and had been exposed to high temperatures. A diagnosis of asteatosis was made in each case, and it was felt that it might be a late sequela of severe prickly heat (miliaria rubra) and was somehow caused by the excessively hot climate.

The patient with anhidrosis, as well as the others, obtained satisfactory relief by using plain greasy ointments and avoiding excessive bathing. Numerous colored photographs of this type of asteatosis, as well as of the starch-iodine demonstration of anhidrosis, were made. It was possible thereby to demonstrate the unique nature of these two conditions to other medical officers.

I should like to congratulate the authors of the article on "thermal anhidrosis" for defining what is apparently a new syndrome. Added to it, however, should be "thermal asteatosis," which may or may not be associated with the anhidrosis and which is commonly the patient's only complaint. Further, physiologic and microscopic study of these diseases will undoubtedly give additional valuable information of the complicated mechanisms of adjustment of the human organism to hot climates.

MODES OF SPREAD OF POLIOMYELITIS

To the Editor:—Since the appearance in THE JOURNAL (Dec. 4, 1943) of an editorial on "The Modes of Spread of Poliomyelitis Virus" some discussion has arisen on several points (Ward, Melnick and Paul, correspondence, February 26). The editorial represented a comment on a paper of Maxcy and Howe, "The Significance of the Finding of Infantile Paralysis Virus in Sewage," which appeared in the *Sewage Works Journal* for November, 1943.

Drs. Ward, Melnick and Paul are chiefly concerned with the editorial but also take exception to a quotation from the summary of Maxcy and Howe's paper, namely that "the disease would not attack children preponderantly, as is the case were it transmitted by the fly or any other insect." While this statement is obviously erroneous as it stands without context in the summary, in the body of the paper the authors quoted from W. H. Frost to the effect that insect transmission of poliomyelitis or any other disease could not give such a preponderance of cases among children in a nonimmune population. This point is a fine one and not well taken, since it is extremely doubtful whether there has ever been any record of a virgin soil epidemic. Nevertheless, as stated in the paper, the role of the fly in the transmission of poliomyelitis is still undetermined.

KENNETH F. MAXCY, M.D.
HOWARD A. HOWE, M.D., Baltimore.

INTERCOSTAL NERVE BLOCK

To the Editor:—In THE JOURNAL, February 19, Dr. E. I. Evans described the method of intercostal anesthesia in the shocked patient and credited it to Bartlett (1940). This method has been described and illustrated in my short monograph on Local Anesthesia (Philadelphia and London, W. B. Saunders Company, 1928, p. 117). It was used during the first world war by a number of military surgeons, notably Franz. The block is especially useful in lateral, subcostal or paramedian incisions, where only one side needs to be injected and where the nerve supply from the other side can be excluded by a subcutaneous infiltration in the midline. It is a simple procedure which, combined with morphine-scopolamine, allows a rapid exploration of the traumatized abdomen. The case reports of Dr. Evans certainly testify for the usefulness of this method under battle conditions. If pentothal sodium could be eliminated it might add to the safety of the procedure, since experienced anesthetists may not always be on hand.

The closure of the abdomen can be facilitated by infiltration of the abdominal muscles and mainly the parietal peritoneum through the abdominal wound.

DISTRICT OF COLUMBIA: Washington, April 17-18. Sec., Commission on Licensure, Dr. G. C. Ruhland, 6150 E. Municipal Bldg., Washington.

FLORIDA: Gainesville, June 8. Sec., Dr. J. F. Conn, John B. Stetson University, DeLand.

MICHIGAN: Ann Arbor and Detroit, May 12-13. Sec., Miss Eloise LeBeau, 101 N. Walnut St., Lansing.

NEBRASKA: Omaha, May 2-3. Dir., Bureau of Examining Boards, Mr. Oscar F. Humble, 1009 State Capitol Bldg., Lincoln.

RHODE ISLAND: Providence, May 17. Sec., Division of Examiners, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

SOUTH DAKOTA: Vermillion, June 4-5. Sec., Dr. G. M. Evans, Yankton.

TENNESSEE: Nashville and Memphis, June 23-24. Sec., Dr. O. W. Hyman, Memphis.

WISCONSIN: Madison, April 1. Sec., Prof. R. N. Bauer, 152 W. Wisconsin Ave., Milwaukee.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice: Failure to Diagnose Osteomyelitis.—The plaintiff was bitten by a coyote, Nov. 30, 1937, receiving a deep puncture wound and abrasions on the back of the hand. The defendant physician was consulted December 2 and placed a "wick," composed of gauze, in the puncture wound to aid drainage and cleaned, dressed and bandaged the hand. This treatment was continued for several days, but the hand became more swollen and painful. By December 10 the plaintiff's condition had become bad, his temperature had risen considerably and he suffered such pain below his left knee that he was unable to leave his home and the physician was obliged to call on him there. The physician diagnosed the pain in the knee and leg as rheumatism and prescribed the internal and external use of wintergreen. The pain did not abate, and the physician next prescribed a hot pad to be placed on the knee and leg. The patient continued to have chills and fever, his temperature remained extremely high, his pain became more excruciating, and his hand, leg and knee became more swollen. The physician then prescribed milk poultices for the hand but the patient steadily grew worse, he could not sleep or rest and finally he became delirious. The physician, however, vetoed any suggestion of hospitalization. Finally, on December 19, neighbors, without the physician's knowledge, took the patient to a hospital in a town about 30 miles from the patient's home in Castle Dale, Utah. At the hospital, Dr. Hubbard took charge of the case and after a general exploratory operation ascertained that the patient had a general septicemia and acute osteomyelitis of the left tibia. Recovery was poor. Four months later the patient was removed to a veterans' hospital in Salt Lake City, where he remained for over a year. By this time he had developed chronic osteomyelitis. About a year later he was admitted to the Marine Hospital in San Francisco, where his leg was amputated at the junction of the middle and lower thirds of the femur. Subsequently the patient

brought suit contending that the physician had been negligent by failing (1) to diagnose the patient's condition correctly as general septicemia and acute osteomyelitis in the left tibia; (2) timely to hospitalize the patient and to operate, and (3) to give blood transfusions, all of which contributed to the patient's loss of his leg, so it was alleged. From a judgment in favor of the patient the physician appealed to the Supreme Court of Utah.

In malpractice cases, said the Supreme Court, to determine whether or not a physician has been negligent in the treatment of a patient, it is necessary to determine whether or not he has used or failed to use the ordinary care and skill required of physicians in the community which he serves. What is the ordinary care and skill required of a physician in the community in which he serves must necessarily depend on expert testimony. There was expert testimony in this case that a physician who used the ordinary skill, care and knowledge required of him in Castle Dale, Utah, in 1937 would have known from the symptoms of the patient and his case history that the patient was suffering from a general blood stream infection and that osteomyelitis should have been suspected. The proper treatment for septicemia at that time and place was to put the patient to bed and see that he had plenty of rest, liquids and a good diet; that the patient be made as comfortable as possible because it is while the patient is sleeping or resting that the body is best able to combat a bacterial infection in the blood stream. The defendant did not instruct the patient to remain in bed and rest, neither did he prescribe plenty of fluids and a proper diet. When the patient complained of pain in his knee and leg defendant diagnosed it as rheumatism and prescribed treatment for that ailment. This, in the opinion of the court, constituted negligence. In arriving at this conclusion the court relied on *Baird v. National Health Foundation*, 235 Mo. App. 594, 144 S. W. (2d) 850, where it was held that it was negligence for physicians to fail to apprise themselves of symptoms which are present and to diagnose and correctly treat the patient on the basis of those symptoms. Regardless of what skill is used, that court held, if a physician fails in his duty to observe and discover a patient's illness, he is negligent. In this case, continued the court, there was sufficient evidence for the jury to find that the physician was negligent in having failed properly to observe the patient's condition and in failing correctly to treat him for a staphylococcal infection by failing both before and after December 10 to prescribe that he remain in bed and rest, take plenty of fluids and eat proper food.

The next question to be determined, said the court, is whether or not the physician was negligent in failing to hospitalize timely and to operate on the patient. At the trial there was evidence that immediately after the patient was taken to the hospital roentgenograms were taken of his leg and knee, that these roentgenograms did not disclose any abnormality and that therefore an exploratory operation was performed, revealing the presence of osteomyelitis in the upper tibia, about 4 or 5 inches being involved. Medical expert witnesses testified that the disease at that time was not in an advanced stage because the roentgenograms did not show any bone involvement. Osteomyelitis, the court observed, is a pus-forming disease which causes decalcification, and the length of time it takes to destroy the bone depends on the virulence of the attacking bacteria. From the fact that only 4 or 5 inches of the tibia had been involved at the time of the operation, the medical expert witnesses were of the opinion that the infection had been localized at that point only a few days. These physicians further believed that earlier hospitalization and operation would not have been beneficial because there is a tendency for the disease when it has localized to wall itself off and it is better to allow that process to continue so that when the operation is performed there will be less likelihood of spreading the infection. From this, said the court, it will be noted that there was insufficient evidence to be submitted to the jury on the question of whether or not the physician was negligent in having failed to hospitalize and operate on the patient sooner.

The patient contended that the physician was negligent in failing to give blood transfusions, since blood transfusions are necessary to combat osteomyelitis. Osteomyelitis, said the court, is a blood stream infection carried within the bone. One medical expert witness testified that when a patient has a badly infected hand due to a coyote bite, suffers from chills and fever, has a general blood stream infection, is very ill, suffers constant pain in his leg below the knee and when that is touched suffers greater pain, he should be prepared for an operation to determine whether he has acute osteomyelitis by being given proper rest, administration of fluids and blood transfusions. Whether blood transfusions are necessary depends on a laboratory test of the blood. Usually in cases of acute osteomyelitis there is a likelihood of a rapid blood destruction; that blood transfusions are necessary to alleviate this condition, and it is dangerous to delay giving blood transfusions because the real danger in acute osteomyelitis is sepsis in the system. Another expert was of the opinion that, unless a blood test showed a destruction of the blood, blood transfusions were not beneficial. The defendant physician had taken no blood test of the patient, and therefore there was no evidence in the record of the actual condition of his blood. However, observed the court, the defendant physician should not be allowed to take advantage of his own failure to act, and we believe there was enough evidence to go to the jury on the question of the negligence of the defendant for failure to prescribe blood transfusions.

The most important question, said the court, however, remains to be settled; namely, was the negligence of the defendant physician the proximate cause of the ultimate injury suffered by the plaintiff? Unless there is evidence showing the causal relation between the negligence of the physician and the ultimate injury there is no liability on the part of the physician. Medicine is not an exact science and it is not necessary that the proximate cause of an injury sustained through the negligence of a physician be proven with exactitude. It is enough if there is substantial evidence to support the judgment. If the injury sustained could be attributed to two or more causes, one of which was the negligence of the physician, it would be a question for the jury to determine which was the proximate cause of the injury. Had the patient pleaded that the physician had negligently failed properly to treat his injuries, commencing from December 2, when he was first employed, instead of only from December 10, by failing to prescribe that he remain in bed, get plenty of rest, take plenty of fluids and eat proper food, which failure resulted in a blood stream infection which in turn caused the osteomyelitis, we are not prepared to say that there was insufficient evidence to go to the jury on the question of proximate cause. Plaintiff, however, based his case on the failure of the physician to recognize that osteomyelitis had set in by December 10 and to treat him for it properly by administering blood transfusions and operating in time. There was no expert evidence in this case that if the physician had done these things at that time the condition which caused the eventual amputation of the patient's leg could have been avoided. No expert witness testified that had the physician recognized the symptoms of osteomyelitis he could have alleviated or cured it by using the ordinary skill, care and knowledge of a physician practicing in that vicinity. As to blood transfusions, one medical witness did testify that it was beneficial in blood stream infections but did not testify that had there been transfusions the end result might have been avoided. Osteomyelitis being a disease the cause and cure of which is peculiarly within the knowledge of medical men and not a matter of common knowledge, it is necessary to have expert testimony concerning the effect of the negligence of a physician on the end result. In this case there was no evidence that anything the physician did or failed to do after osteomyelitis developed caused the end result. In the absence of such expert testimony there is nothing on which a jury can base its finding on the proximate cause of the injury. A jury may not conjecture or speculate but must have substantial evidence on which to base a verdict. The judgment in favor of the patient was accordingly reversed and a new trial was ordered—*Anderson v. Nixon*, 150 P. (2d) 216 (Utah, 1943).

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1934 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Diseases of Children, Chicago 67:1-88 (Jan.) 1944

*Prophylaxis of Measles with Convalescent Serum: Principal Factors Influencing Results. M. Stillerman, H. H. Marks and W. Thalhimier.—p. 1.

*Attack Rate and Incubation Period of Measles: Significance of Age and of Conditions of Exposure. M. Stillerman and W. Thalhimier.—p. 15.

Immunity to Tetanus Induced by Third Dose of Toxoid Three Years After Basic Immunization: Based on Study of 38 Allergic Children. M. M. Peshkin.—p. 22.

Subclinical Vitamin Deficiency: VI. Thiamine in Skeletal Muscle of Infants and Children. Mildred Carleen Hulke, N. Weissman, Virginia Rowland, R. Gross and J. W. Ferrebee.—p. 30.

Hypervitaminosis A and Carotenemia. H. W. Josephs.—p. 33.

Tularemia Meningitis: Report of Case and Summary of Previously Reported Cases. J. K. David Jr. and J. N. Owens Jr.—p. 44.

Use of Evaporated Milk without Added Sugar for Feeding of Infants. H. McCulloch.—p. 52.

Convalescent Serum in Prophylaxis of Measles.—Stillerman and his associates investigated the measles-protective properties of convalescent serum and the factors that influence the results of its use, such as age of contact, dosage of serum, interval between exposure and injection, and duration and intimacy of exposure. Since a certain proportion of susceptible persons normally escape infection, allowance has been made for this on the basis of a control study of contacts who have not received injections. From 1938 to 1941 a group of 502 intimately exposed susceptible family contacts from 6 months to 15 years of age were given injections of convalescent measles serum. A group of 245 subjects of similar ages who had not received convalescent serum served as controls. In the control group the rate of immunity varied with age. Of children 6 months to 11 months of age one third did not have measles on first exposure; of those between 1 and 7 years 10 to 14 per cent escaped the disease; of those from 8 to 9 years of age 31 per cent were immune, and of the small group between 10 and 15 years of age 85 per cent were immune. Complete protection was obtained by 50 per cent of the 502 children. Modified measles occurred in 49 per cent and unmodified measles in 1 per cent. The rate of complete protection, analyzed according to the interval between the exposure and the injection, showed no significant difference between the fourth and the seventh day. However, on the eighth day after exposure, even though the serum had a definite modifying effect, it did not prevent measles. Mild complications developed in only 5, or 1 per cent, of the 502 contacts who received injections of serum. Complete protection is recommended for all exposed healthy susceptible children under 2 years of age, because it postpones the attack until they are older, when there is a reduced case fatality rate, and is advised also for contacts over this age who are acutely or chronically ill. Modified measles is indicated for healthy children over 2 years of age, because this condition is a mild disease rarely associated with complications and is followed by strong and lasting immunity. For complete protection the optimum dose after an exposure of four to seven days is 10 cc. for contacts 6 to 11 months of age, 15 cc. for those 12 to 23 months and 20 cc. for those 2 and 3 years of age. For healthy contacts 4 years and over, complete protection is not worth striving for. If modified measles is desired, 5 cc. is sufficient between the fourth and the eighth day after exposure for contacts up to 24 months of age, and 10 cc. for those older.

Attack Rate and Incubation Period of Measles.—Stillerman and Thalhimier studied certain aspects of the attack rate of measles in 266 intimately exposed susceptible family contacts 1 month to 14 years of age. Their observations were made in

the 1940-1941 epidemic in New York City. They found that the secondary attack rate was 75 per cent. Age was the principal factor influencing the secondary attack rate of intimately exposed children. This attack rate was lowest for children in early infancy, highest for those 1 to 7 years of age (80 to 90 per cent) and sharply lower for those in the 10 to 14 year group (15 per cent). Of 21 children 6 months to 10 years of age who escaped measles on one exposure and were reexposed, about one half contracted the disease. Hospitalization of patients after the appearance of the rash did not lower the secondary attack rate of the intimately exposed susceptible children. An increased intensity of exposure as measured by simultaneous contact of susceptible children with more than 1 patient with measles in nine families did not increase the incidence of the disease. The incubation period of measles was ten to fourteen days for 80 per cent of the contacts, fifteen to nineteen days for 14 per cent and less than ten days for 6 per cent. The proportion of patients with an incubation period of fifteen days or more was significantly greater in the 12 to 23 month age group.

Trial Experiments on Use of Para-Aminobenzoic Acid to Inhibit Toxic Reactions in Treatment of Neurosyphilis with Pentavalent and Trivalent Arsenicals: Report of Failure to Prevent Secondary Reactions. A. S. Rose, L. D. Trevett, H. C. Solomon and J. H. Sandground.—p. 103.

Treatment of Latent Syphilis.—Discker and his associates define latent syphilis as that stage of infection in which the patient, having no symptoms or physical signs of syphilitic disease, is recognizable as syphilitic only by means of a positive laboratory test of the blood. The only justification for submitting him to the risks of antisiphilitic treatment is for the protection of public health (of importance only if his infection is recent) and for the purpose of preserving his health and of preventing the development of late manifestations of syphilis. In the material reviewed the diagnosis of latent syphilis rested on (a) repeated positive blood serologic tests (the vast majority of cases), (b) in seronegative patients a reliable history or (c) in seronegative women the birth of a syphilitic child. Excluded are all patients with originally abnormal spinal fluids because of the wide difference in prognosis of latent syphilis and asymptomatic neurosyphilis. Among 5,326 patients with latent syphilis admitted to the medical clinic of the Johns Hopkins Hospital between 1914 and 1934 there were 926 who were observed for more than five years. These are a fairly representative sample of the total group. The final status was evaluated by physical examinations and in many patients by repeated cerebrospinal fluid examinations and radiologic study of the cardiovascular stripe. Progressions were higher among men than among women, but the differences were within sampling variation. Cardiovascular progression was more frequent among Negro men and neurosyphilis more frequent among white men. Progression was no more frequent among seroresistant patients than among those whose blood serologic test reversed in the first year of observation. Parous women progressed less frequently than did nulliparous women or men, but usually they received more treatment. Neuroprogression was approximately the same in all age groups. Benign late syphilis appeared predominantly in the age group under 30, cardiovascular syphilis after this age. The

highest proportion of progression occurred among patients receiving under fifteen arsenical injections and a corresponding number of heavy metal injections. Progressions were no more frequent among patients receiving fifteen to nineteen injections than among those receiving more treatment. The optimum amount of treatment to reduce progression to a minimum is approximately twenty injections each of an arsenical and a heavy metal.

Dark Field Examination of Lymph Nodes in Syphilis.—Loveman and Morrow studied the value of the examination of lymph nodes for *Treponema pallidum* by dark field. They decided to determine (1) the accuracy of this method, (2) the percentage of additional positive dark fields they could obtain with it, (3) whether or not the method could be employed in an army hospital and (4) whether, if nonpathogenic spirochetes were encountered, they were a source of confusion with *Treponema pallidum*. The authors made studies on 40 patients, 25 of whom had syphilitic lymphadenopathies and 15 had various types of nonsyphilitic lymphadenopathies. The technic of aspirating the contents of lymph nodes is as follows: The skin overlying the node to be aspirated is painted with any suitable antiseptic, such as tincture of iodine, metaphen or merthiolate. With use of a 20 to 22 gage needle, about 0.5 cc. of sterile distilled water is drawn up into a 5 to 10 cc. Luer syringe. The suitable node is then fixed with the fingers of one hand so as to prevent it moving away from the needle when the puncture is attempted. The needle is then inserted directly into the node. When it is certain that the node substance has been pierced, the water is injected. The needle is then rotated for thirty or forty seconds and the node is gently moved from side to side; then withdrawal of a slightly blood tinged serum is possible. A small drop is placed on a glass slide and the search is made for spirochetes. The technic is simple and easily mastered. The authors found that in every patient in whom the dark field of the local lesion was positive for *T. pallidum* and the nodes were sufficiently enlarged to permit aspiration the dark field examination verified the local findings. By employing aspiration dark field of lymph nodes the authors were able to increase the percentage of immediate diagnosis from 28 to 76. In neither syphilitic nor nonsyphilitic lymph nodes were spirochetes other than *T. pallidum* encountered.

Experiences in War Surgery in China. P. E. Adolph.—p. 134.

Depressor Nerve Impulses in Shock.—Phemister and his collaborators found that stimulation of the aortic-depressor nerve of the rabbit may maintain the blood pressure at shock levels for hours without serious impairment of the circulation or of the body tissues. However, if continued for a longer period it may produce death from the effects of hemodilution, anoxia and damage to the vasomotor centers, a condition which may be designated as neurogenic shock. Plasma proteins are lost from the blood apparently as a result of capillary damage. Judging by the relative harmlessness of these long periods of low blood pressure in rabbits, by the inability to produce more than a brief slight lowering of blood pressure by direct stimulation of somatic nerves which carry impulses from traumatized fields and by the comparatively short duration of the periods of reflex lowering of blood pressure during syncope and abdominal manipulations, it is extremely improbable that "primary shock" is ever produced in man by the action of afferent depressor nerve impulses. The use of the term "primary shock" to denote such a condition should be abandoned. When the blood pressure of the rabbit was first lowered to shock levels by hemorrhage and

the aortic-depressor nerve then stimulated, the additional lowering of blood pressure would tend to hasten death to some extent. Also when the blood pressure was first maintained at shock levels for periods of one to four hours by aortic-depressor nerve stimulation and the rabbits then bled, there was usually some reduction in ability to tolerate loss of blood. Judging from the results of combining hemorrhage and aortic-depressor nerve stimulation in lowering blood pressure and producing shock in rabbits, the occurrence in man of fainting or of a reflex fall of blood pressure from abdominal manipulation in the presence of low blood pressure produced by hemorrhage may constitute a contributing factor to shock. Clinical experience also supports this contention to some extent.

Blood Volume Changes in Traumatic Shock.—Evans and his collaborators estimated the plasma volume in patients who were in shock as a result of various types of trauma. They also attempted to correlate these blood volume studies with the manifestation of signs of shock in these patients. It was their aim to determine the relative importance of blood loss as an initiating and sustaining factor in traumatic shock. They had clinical shock material similar to that seen in modern warfare. One of their hospitals cares for a large urban Negro population, among which knife and gunshot wounds of the extremities, chest and abdomen are frequent. The authors also studied a considerable number of traumatic injuries of the skeletal structures caused by automobile and industrial accidents. With use of the Gregersen-Gibson method for the estimation of plasma volume, it has been found that signs of severe shock do not ordinarily appear unless the blood loss is greater than 15 per cent. The average blood loss in severe traumatic shock has been about 38 per cent, no matter what the nature of the trauma. Analysis of dye disappearance curves revealed no evidence of increased generalized capillary permeability in traumatic shock. From hematocrit studies it is evident that what is lost early in traumatic shock in the zone of injury is whole blood, not plasma. Severe depletion of blood volume appears to be the most important single factor in the causation of traumatic shock. A decline in blood pressure levels is the most valuable clinical sign in the early diagnosis of clinical shock.

Liposarcoma: Malignant Tumor of Lipoblasts.—Stout records the group of 41 cases of liposarcoma which have accumulated in the Laboratory of Surgical Pathology of Columbia University during the past thirty-seven years and integrates the information gained from them with what can be gleaned from 134 previously reported cases. These tumors tend to form large bulky masses, with a predilection for the thigh and extra-peritoneal tissues but with occasional appearance in many other regions. They exhibit great variations in speed of growth, they are sometimes multiple and the more malignant forms metastasize usually either to the lungs or to the liver. These tumors are frequently mottled with yellow because of their lipoid content and are often slimy from the formation of mucoid material. Microscopically they can be divided into one well differentiated, less malignant group which simulates the appearance of ordinary embryonal fat and three other poorly differentiated more malignant groups resembling respectively atypical ordinary embryonal fat, atypical brown fat with the formation of rounded lipoblasts, and finally a group showing these two elements in combination. Probably as a result of metaplasia these tumors can on occasion form other tissues such as reticulin and bone. This versatility suggests that there are probably not separate embryonal stem cells for adipose tissue and brown fat but that the two spring from a common ancestor segregated from the primitive mesenchyme.

Lymphosarcoma of the Gastrointestinal Tract.—McSwain and Beal review 20 cases of lymphosarcoma of the gastrointestinal tract that were treated in the New York Hospital during the past nine years. The number of carcinomas of the gastrointestinal tract seen during this period shows that there is 1 case of lymphosarcoma to every 51 cases of carcinoma. All areas of the gastrointestinal tract except the duodenum were involved. There was 1 lymphosarcoma of the esophagus, the stomach was the site of the lymphosarcoma in 7 patients, the small intestine in 3 patients, the appendix in 2 patients and

the large intestine in 7 patients. Lymphosarcoma of the gastrointestinal tract is rarely recognized before operation. The survival of the patient is influenced more by the site and extent of the growth than by the histologic type of neoplasm or the age of the patient. The prognosis depends largely on whether the lymphosarcoma is localized and can be treated as an isolated lesion or whether a general spread has occurred. The 6 patients in whom the lesion was sufficiently localized to allow extirpation have survived from two to seven years without receiving roentgen therapy. Of the 6 patients given roentgen therapy alone, only 2 are without evidence of recurrence. In 2 cases resection of the lesion was followed by irradiation without evidence of a return of tumor. In 4 resection followed by irradiation gave poor results. In 1 case irradiation was started five months after operation, obviously too late for maximum prophylactic value; in another case the therapy was tolerated so poorly that it was discontinued. Nine patients are alive and well at present, without evidence of recurrence from one year to nine years and five months since the diagnosis was established. The mortality at present is 42 per cent (9 of the 19 cases followed). In eight patients who died, the average duration of life was twenty-four months.

Atypical Pneumonia of Unknown Etiology.—Lusk and Lewis studied the syndrome variously designated as primary atypical pneumonia, nonbacterial bronchopneumonia, virus pneumonia, pneumonitis, interstitial pneumonia or interstitial bronchopneumonia. While its causative agents are unknown, its kinship clinically, roentgenologically and pathologically with the group known to be of virus origin, such as influenza A or B or ornithosis (psittacosis), justifies speaking of it as a virus disease. It should not be considered a new disease, having been found in sections of lungs removed from soldiers during the Civil War (MacCallum) and preserved in the Army Medical Museum. The pathologic aspects resemble those seen in the influenzal and streptococcic pneumonias and empyemas occurring in military camps in 1918. The authors set up criteria to

which the syndrome must conform before a diagnosis of atypical pneumonia of unknown etiology can be made. They studied (1) the physical and x-ray findings in atypical pneumonia, (2) the pathologic changes as seen in their own patient who died with atypical pneumonia and that submitted to them by the Army Medical Museum and (3) the types of pneumonia they observed in measles and scarlet fever. Their impressions are based on a critical analysis of about 500 patients who represented a cross section of some 6,000 cases of acute epidemic respiratory tract infection in the admissions to the Station Hospital, Fort Custer, Michigan, from Dec 1, 1942 to June 1, 1943. Studying these 500 cases they observed that 60 per cent terminated during the period of invasion without involvement of the lungs, 15 per cent justified the diagnosis of bronchitis based on physical findings and 25 per cent presented pneumonia proved by x-ray examination. The authors emphasize that atypical pneumonia should not be considered a disease entity but part of a syndrome in which the pulmonary lesions are but one manifestation of a generalized infection. So considered it might well be a physiologic accident and not a pneumonia in the accepted sense of the term. It is an interstitial pneumonitis, and the pathologic changes are similar to those found in other virus infections of the pulmonary tract.

Cup Assay for Penicillin.—Foster and Woodruff say that the publication of this paper was prompted by the numerous inquiries pertaining to details of the cup assay procedure following the appearance of their recent article discussing the principles, advantages and disadvantages of the various methods of assay for penicillin. The inquiries revealed that numerous features of the test which are taken for granted by workers experienced with this method are quite unknown to the great majority of people who assay penicillin and that there is no source in the literature where details of the complete procedure are available. This paper is intended to provide such information. It contains also a number of points of practical efficiency value which have evolved in a laboratory that handles 100 to 400 cup assays in quadruplicate daily. The principle of the assay is that originally described by the Oxford group, but the procedure has since undergone substantial modification. The authors evaluate the H strain of *Staphylococcus aureus* and a strain of *Bacillus subtilis* for the cup assay. They describe the preparation of the spore inoculum, the preparation of the plates, the setting up of the cups and samples, the measurement of the inhibition zones and the calculation of the results.

Abnormal Uterine Bleeding After Middle Age.—Mussey and Wilson review the records of 200 women who registered at the Mayo Clinic between July and September 1937 because of abnormal uterine bleeding. The cases were selected from 1937 so that the results of treatment could be reviewed after an interval of five years. Many women past the age of 35 or 40 view abnormal bleeding as a manifestation of "change of life" and fail to consult a physician. This results in many avoidable deaths. Although abnormal vaginal bleeding may occur without implying serious organic disease, no patient past the age of 35 years who notes abnormal uterine bleeding, especially metrorrhagia, should be dismissed until it is reasonably certain that a malignant condition does not exist. Women with such symptoms should not be given endocrine therapy until malignant disease has been ruled out. Many of the causes of abnormal vaginal bleeding can be discovered by thorough pelvic examination. This should include inspection of the urethral meatus and vaginal introitus and bimanual palpation of the cervix, uterus and adnexa. Examination of the vagina by speculum, with direct visualization of the mucous membrane and cervix, never should be omitted. Biopsy should be done of any lesion which arouses suspicion. Except in pregnancy, diagnostic curettage should be used in every instance in which there is doubt about the character of the uterine contents. The conditions responsible for the bleeding have been divided into benign, functional, malignant and postmenopausal conditions. After discussing these different conditions and their treatment the author says that, although a review of 200 cases should give a good sampling, relatively atypical proportions were found of (1) minor benign conditions causing abnormal uterine bleeding, (2) more severe benign conditions requiring hysterectomy or irradiation and (3) carcinoma of the uterus. In an average office practice one should encounter a much larger proportion of minor conditions, proportionally fewer cases of fibromyoma and a still smaller proportion of malignant lesions. The authors found 80 cases (40 per cent) of uterine fibromyoma and 27 cases (13 per cent) of carcinoma of the uterus. Uterine bleeding in the presence of fibromyoma is usually successfully treated by hysterectomy if the patient has not reached the age of 40 or 42 years, to preserve ovarian function. Hysterectomy is done at any age if the tumor is larger than a uterus two and half to three months pregnant. Patients who are more than 42 years of age and whose uterus is smaller are given a dose of radium sufficient to bring on the menopause. Aside from exceptional cases, curettage should be performed prior to radium treatment. Radium, when used to control menorrhagia associated with fibromyoma, stopped the excessive bleeding in all but 2 of 17 cases. The results of total hysterectomy for carcinoma of the body of the uterus, with a rate of cure of 63 per cent, appears to justify continuance of this treatment. The rate of cure of 37 per cent for carcinoma of the cervix following irradiation with radium and x-rays conforms to the usual results. The curability of early carcinomatous lesions is much greater than the curability of the more advanced. In a large majority of cases the warning sign of abnormal uterine bleeding was ignored too long.

Venous Thrombosis in Obscure Visceral Carcinoma.—Cooper and Barker point out that the spontaneous development of thromboses in the peripheral veins may be a definite presumptive sign of the presence of obscure visceral carcinoma. They describe 4 cases to illustrate the connection between visceral carcinoma and peripheral thrombophlebitis. They conclude that: 1. Visceral carcinoma is often the predisposing factor in the development of multiple, and sometimes distant, venous thrombosis. This seems particularly true in cases in which the neoplasm arises from or involves the body or tail of the pancreas. 2. In the absence of other obvious causative factors, the development of apparently spontaneous peripheral thrombophlebitis when the patient is 50 years or more or age should suggest a careful search for visceral carcinoma. 3. The formation of a thrombus in many of these instances would appear to be the result of more than simple mechanical obstruction, circulatory stasis or alteration in the structure of the vessel wall. Further study of the factors influencing the coagulation of the blood would seem indicated.

 Sulfapyridine Anuria. R. E. Waterston and C. C. B. Doherty.—p. 549.

Autoagglutination After Sulfapyridine.—According to Parekh, agglutination of a person's red corpuscles by his own plasma or serum is rare. Nevertheless, in human beings this phenomenon has been observed in chronic mitral endocarditis with bronchopneumonia, during convalescence from pneumonia, in trypanosomiasis, in cirrhosis of the liver, in relapsing fever, in syphilis, in epilepsy, in certain forms of icterus due to hemolysis, in secondary anemia, in pernicious anemia after sulfanilamide administration and in snake poisoning. The author reports the history of a man aged 35 in whom autohemagglutination followed the administration of sulfapyridine for a respiratory infection. The agglutination was most noticeable in the cold and was feeble or inactive at 37 C. The process of autoagglutination is reversible.

Tropical Ulcers.—Bharucha reports a series of 179 cases of cutaneous ulcer. His aim was to investigate the cause and to shorten the period of hospitalization. Poor diet, especially one deficient in proteins, calcium and vitamins B and C, also excessive humidity and excessive rainfall, specific organisms such as fusiform bacilli and a high incidence of syphilis have each in turn been labeled as the cause of these ulcers. Weighing all the evidence at his disposal, the author concludes that these so-called tropical ulcers are not caused by a specific organism. He concludes that they started as small injuries which were neglected and became septic. Many of these soldiers after the receipt of minor injuries continued to take part in the training schemes, and they had to continue wearing boots and puttees and had few opportunities for cleaning the injured part or keeping it at rest. He suggests that every soldier who receives any injury, however trivial, should have an opportunity to get the wound cleaned and dressed at the earliest possible moment and be exempt from such duties as involve the constant use of the injured part till healing is complete. Force is added to this suggestion when it is seen that these 179 patients spent in all 6,056 days in the hospital. This does not include the time before admission to the hospital during which they were not fit to work and the time spent by many of them at the convalescent depot.

- *Diagnosis and Treatment of Yaws Among West African Troops. W. H. H. J. De Wyt.—p. 255.
 Control of Malaria: East Africa Command, 1940-1943. D. B. Wilson and A. R. Melville.—p. 263.
 Common Anorectal Conditions in Army. H. S. Shucksmith.—p. 269.
 Management of Lung Disease of Uncertain Diagnosis. T. Lee.—p. 278.

Treatment of Yaws.—De Wyt analyzes 72 cases of yaws. A table which classifies the cases shows that with the exception of 2 cases of primary yaws all other cases were tertiary. The salient feature of this series is the large proportion of foot yaws, which accounted for 66 per cent of the total. In 33 of the 43 cases of foot yaws a history of intermittent disability with exacerbations during the rainy season was obtained. The diagnosis was based on the presence of "pitting," the hypertrophic epithelium, the history of exacerbation during the rains and the positive Kahn test. Neoarsphenamine and sodium potas-

sium bismuthyl tartrate were used in the treatment. In all 9 cases were treated with neoarsphenamine, the course consisting of an initial dose of 0.45 Gm. followed by weekly doses of 0.6 Gm. up to a total of twelve injections. The remaining cases were treated with intravenous sodium potassium bismuthyl tartrate, the course being twelve weekly injections of 1 grain (0.065 Gm.). The solution used was made in the hospital dispensary with a concentration of 1 grain in 2 cc. of distilled water. The intravenous route was preferred to the intramuscular, as the latter can be very painful and may render the patient temporarily incapable of full duties. Since the exhibition of sodium potassium bismuthyl tartrate may produce renal damage, the urine was tested twenty-four hours after each injection. Persistent albuminuria in 3 cases cleared up after the treatment was changed to neoarsphenamine. Clinical cure was obtained in all 72 cases. The author points out that the treatment recommended by most workers for yaws in adults is three injections of one of the arsenical or bismuth preparations. Many do not seem to realize that, although there is about 50 per cent of cures with this dosage, there is also a high relapse rate. The blood reaction in yaws is known to be very unresponsive to treatment, and it seems reasonable to suppose that this is because the treatment is not carried out for a long enough period. A similar state of affairs obtained in the early days of the arsenical treatment of syphilis, when apparent cure after a few injections was followed later by a recurrence of the disease. It is now known that the treatment of syphilis must be continued until the blood reaction is negative, and it is probable that the same thing is true of yaws.

- *General Telangiectasis Angioma. E. Martinez Zuveria and I. Naput.—p. 68.
 Required Conditions for Normal Feeding: Diet in Dermatoses in Children. B. Soria.—p. 74.

Multiple Telangiectasis Angioma.—Martinez Zuveria and Naput's patient presented, at birth, multiple telangiectasis angioma which covered the entire surface of the body, including the palms of the hands, soles of the feet and the scalp. Frequent hemorrhages occurred as the result of rupture of the angiomas. The clinical diagnosis of telangiectasis angioma was confirmed by the results of a biopsy. The tests for syphilis in the parents and in the infant gave negative results. During the first four months of the patient's life the angiomas increased in number and size. A hydrocele appeared. The therapy consisted in acetylarsan administration followed by ultraviolet irradiations. The hydrocele was reabsorbed. The angiomas slowly disappeared and the skin became normal within ten months. This is the first case of multiple telangiectasis angioma with entire disappearance from the skin which has been reported in the literature.

- *Apex Beat in Mitral Stenosis. P. Cossio.—p. 145.

Apex Beat in Mitral Stenosis.—Cossio carried on simultaneous records of the apex beat and of the heart sounds in 10 normal persons, 10 patients with mitral stenosis and 20 patients with various heart diseases (arterial hypertension, auricular fibrillation and nodal rhythm). Two different movements can be distinguished in the early systolic part of the apex beat record, namely a slow beat which is due to initiation of the ventricular systole and a rapid vibrating impact which is due to the systolic tension of the auriculoventricular valves during occurrence of the first heart sound. In normal conditions beat and impact are synchronous, whereas in mitral stenosis the slow beat precedes the rapid vibrating impact. This phenomenon is of almost pathognomonic value. It can also be perceived by palpation. It is attributable to the retarded closure and tension of the mitral valve (first sound) due to the low initial tension of the mitral valve at the beginning of the systole, which is caused by the hemodynamic conditions which exist in mitral stenosis.

Book Notices

Applied Dietetics: The Planning and Teaching of Normal and Therapeutic Diets. By Frances Stern, Chief of Frances Stern Food Clinic, The Boston Dispensary, Boston. Second edition. Cloth. Price, \$4. Pp. 265. Baltimore: Williams & Wilkins Company, 1943.

This edition of a standard manual is based on the methods developed in the Food Clinic of the Boston Dispensary. The first edition was dated 1937. The new edition uses the same mode of presentation as the first but includes the results of later research in nutrition and its application in modern dietetic practice. Most of the information is presented in tabular form. There are fifty-seven tables. These tables present the information about foods and diets from various points of view. Beginning on page 210 and extending through page 255 is a series of tables beginning with summaries of the normal diet in terms of meals for the day for the adult and the child, followed by similar tables for allergic persons, those with spastic constipation, colitis, ulcers, underweight, overweight, diabetes, liver disease, ketogenic diets, nephritis, pregnancy and tables showing typical normal diets and the variations for abnormal conditions. These tables would be more useful if they were numbered. The book includes dietary outlines for the management of normal diets, food allergies and other conditions for which tabulations have been listed. A typical outline is that for atonic constipation, which occupies practically two pages and is dealt with under the headings part of body affected, physiology, abnormal conditions, contributing factors, laboratory data, dietetic treatment, food constituents, foods (foods used, as distinguished from the others for special contributions), meals, environmental factors that influence the effectiveness of the diet, education of the patient, abnormal conditions and diseases that may be found in association with atonic constipation. There is a long series of tables to assist in simpler computation of the diet. These tables are numbered. There is an excellent chapter on the education of the patient on the normal diet.

This book should be invaluable in any hospital dietary department, in the teaching of dietetics to nurses, in the training of dietitians, and as a reference book for physicians in whose work dietary factors are important.

The Boy Sex Offender and His Later Career. By Lewis J. Doshay, M.D., Ph.D., Psychiatrist, Children's Courts, New York City. Foreword by George W. Henry, M.D., Associate Professor of Clinical Psychiatry, Cornell University Medical College, New York. Cloth. Price, \$3.50. Pp. 206, with 12 illustrations. New York: Grune & Stratton, 1943.

Dr. Doshay is an experienced psychiatrist and has worked with juveniles for a considerable period. Most of this present study deals with 256 juvenile sex offenders who have all appeared in court clinics of New York during a six year period. This is an adequate sample because of the small number of juvenile sex offenders that come through the court. The report covers a six year period of study and tends to cover every aspect of the history of the environmental contacts, including parental attitudes. Such factors as nationality of parents, status of the home and sibling relationships are touched on, but friction between the parents is also covered in certain aspects. Other types of factors to which attention is given are community factors, including the neighborhood, recreational and school facilities. The second part of the book deals with the personality of the sex delinquent, including what the author calls "inherent traits," which are age, race, intelligence quotient, disorders of the mind and bodily disorders of temperament, and some attention is given to what the court has done with juvenile offenders. The author concludes with a discussion of adult successes and failures. There are two concluding chapters, one in which the author gives the derived conclusions with a list of twelve questions such as "Do the findings of the study warrant the transfer of management and treatment of juvenile sex offenders from the courts to the community agencies?" The answer to this question is that the question will find answer in the next chapter. The final chapter deals with predicting treatment and prevention. Probably the most important conclusion to which the author comes, based on his mass of statistical material, is that the juvenile sex delinquent boy seems to be self curing. This is an important conclusion. The court clinic in Detroit

has pointed this out again and again, but Doshay's findings, based on juveniles including six years of careful follow-up, stresses this important fact. Much of the statistical material that Doshay prints is not worthy of the attention he gives it. The figures and tests of validity are not applicable to those statistics. Some of the distributions are spread so thin that no conclusions can be drawn from them. All in all, however, this very careful and well written survey gives a general impression about the male juvenile sex offender which those having to do with such cases should find interesting.

A Practice of Orthopaedic Surgery. By T. P. McMurray, M.B., M.Ch., F.R.C.S., Professor of Orthopaedic Surgery, Liverpool University. Second edition. Cloth. Price, \$7. Pp. 435, with 191 illustrations. Baltimore: William Wood & Company, 1943.

The author's objective is the instruction of young surgeons and final year students in the basic principles of orthopaedic surgery. He has adhered to unadulterated orthodox practice. The section on the knee reflects the opinion of a recognized authority with an extensive training and experience. The McMurray test has been found helpful in the diagnosis of many cases of internal derangements of the knee. Much can be learned from a carefully taken history of the injury. The occurrence of pain and its exact site are of importance, and the joint must be carefully palpated to localize any area of tenderness. The stability of the lateral and crucial ligaments must be tested and the full range of painless movement carefully measured. The whole surface of the joint should be palpated while the patient bends and straightens it through its fullest possible range. Radiographic examination of the joint in at least two planes at right angles to each other is of the greatest help.

If in spite of the most careful routine examination the diagnosis is still in doubt, various accessory methods can be employed, of which the following has proved itself to be the most reliable: This method of examination by manipulation is of particular value in those injuries to the cartilage in which the lesion involves the meniscus at or behind the middle of the joint. Lesions of the cartilage in this region do not give rise to the classic syndrome of "locking" and "unlocking" because any reduplication of the broken portion of the cartilage produces a block to flexion rather than to extension of the joint. When the test is correctly applied, not only can the presence of a lesion be determined but its exact site can be mapped out with comparative certainty. During the examination the patient must be recumbent and relaxed; the surgeon, standing on the side of the injured limb, grasps the foot firmly, while the knee is bent to its fullest possible range until the heel approaches or touches the buttock. The foot is now rotated externally and the leg adducted at the knee. With the leg and foot at this angle, the knee is slowly extended. With the alteration of the angle of the joint, any loose portion of the internal cartilage is caught between the articular surface of the femur and tibia, and the sliding of the femur over the abnormal portion of the cartilage is accompanied by an appreciable click and pain, which the patient states is the same that he has already experienced when the knee gave way. The examination should be completed by a similar extension of the knee from full flexion while the foot is rotated inward and the leg adducted. If no click can be produced by these movements properly conducted, it may be safely considered that the internal cartilage is normal posteriorly. If a click is produced it is possible to determine, from its severity and the angle of the joint at the time of its occurrence, the size of the broken portion of the cartilage and its site in the cartilage substance.

Occasionally when the patient is particularly nervous the examination cannot be properly completed without the help of general anesthesia.

Health for the Having: A Handbook for Physical Fitness. By William R. P. Emerson, A.B., M.D., Professor of Pediatrics, Tufts College Medical School, Boston. Cloth. Price, \$1.75. Pp. 116. New York: Macmillan Company, 1944.

The title of this book promises more than the book delivers. The health problem is not so simple that one can speak justifiably of "health for the having." Especially is this true when it develops that the book is built on ideas which were current in health education immediately after the first world war. There

He thinks that the simple passage of these organisms through the urinary tract causes a reaction sufficient to precipitate an attack of herpes.

Some such slight disturbance of health may have brought on the attack of herpes in the case described. A hidden infection may have taken place, causing sufficient disturbance to bring out the herpes but not at the time causing other symptoms. During the following week sensitization to the infecting germ or virus developed, as occurs in so many diseases, and the fever resulted. If the infected area had been in the upper air passages, the extension to the ear drum and submaxillary gland could easily have occurred. The second skin lesion, on the finger, may have been a second herpes lesion or a complicating impetigo cut short by the ointment.

RECURRENT BLOODY PLEURAL FLUID WITH REPEATED ESCAPE AND REABSORPTION IN CHEST WALL

To the Editor:—A woman aged 54 has had a chronic cough for several years. There is no history of tuberculosis. She has had vague digestive trouble for six months and has lost 20 pounds (9 Kg.). She has a pigmented mole measuring 1 by 2 centimeters over the right ilium. The patient was seen after she had had a sudden severe attack of pain in the right dorsolumbar region. The temperature was 99.5 F. There were no dyspnea, no aggravation of the cough, some pain on deep breathing but more on motion of the back. No abnormalities were discovered in the lung. My diagnosis was lumbago. I made a third visit nine days later and found the right side of the chest full of fluid and the patient had considerable mechanical difficulty with respiration. She was tapped of 1,500 cc. of bloody fluid. This fluid gave negative results on culture and smear, negative guinea pig inoculation for tuberculosis and no tumor cells. For two and a half months she was tapped on an average of once in four to five days of the same bloody fluid in quantity from 500 to 2,500 cc. Indication for tapping was increasing dyspnea. Eighty days after onset I received an urgent call to tap the fluid. However, when I arrived she was improved and I discovered that the right breast was full of fluid and this swelling rapidly spread into the axilla and down as far as the crest of the ilium. Since that time she has not been tapped again but undergoes the following sequence of events: The fluid gradually absorbs, the dyspnea increases until it is quite severe, she has a coughing spell, the fluid again fills the subcutaneous tissues and the dyspnea is relieved. Prior to this dramatic change in events the patient was rapidly failing but since then, since she no longer loses this large amount of nourishment, she has been gradually improving and is now in good condition except that the chest is full of fluid and she is unable to sit up or lie on the left side. Her appetite is excellent, digestion is good and she has no complaint except dyspnea when the chest fills. She has never been able to sit up for x-ray examination, and the films show only a chest full of fluid. Physical examination at present reveals the entire chest flat to percussion; the heart and mediastinum are shoved over, depending on the amount of fluid; the heart irregular, sounds are clear and the rate is moderate; there are no tumors in the abdomen; vaginal examination is negative; reflexes are normal; the Kahn test for syphilis is negative. The pigmented mole shows no sign of activity. Temperature is normal. My first diagnosis was cancer of the lung or pleura. However, it is now eight months since the onset, and the improvement in the patient's condition now makes me doubt that diagnosis. The sudden onset suggests embolism, but I have been able to discover no source of a possible embolism. Might such a condition be caused by an aseptic infarct of the lung? The fluid is strongly blood tinged, in fact quite opaque.

Escape of chest fluid in this way must be unusual. Presumably it escapes through the multiple puncture holes or a tumor is invading the chest wall.

C. H. Holliman, M.D., Watsonville, Calif.

ANSWER.—The case described is certainly unusual. When one encounters bloody fluid in the pleural cavity one thinks of three things: tumor, which accounts for probably 90 per cent of cases; tuberculosis, which accounts for an occasional case, and infarct, which accounts for a few cases. The fact that the patient is improving after eight months is against tumor. Infarct usually clears rapidly and the fluid absorbs in a few weeks. Negative smears and guinea pig inoculations do not absolutely rule out tuberculosis.

Spontaneous drainage into the tissues of the chest wall is rare in aseptic effusions. The repeated spontaneous drainage of the kind described here is difficult to understand. Ordinarily the tissue spaces become indurated and scarred and fail to absorb fluid after the first few weeks.

The indications appear to be to aspirate the fluid more rapidly than it reforms and eventually rid the pleural cavity of all fluid. This could be done over the course of a few days. Some air might be reinjected to prevent too great change in the pleural pressure. An x-ray film could then be taken with the patient in the sitting position. The fact that the patient's mediastinum is pushed far to the opposite side is a definite indication for more complete and frequent aspiration.

No patient should be considered too ill to have an x-ray film in the sitting position. In cases of this kind it is frequently extremely difficult to make a certain diagnosis. As long as the patient is afebrile and the fluid is sterile the only treatment indicated, whatever the condition, is repeated aspiration and

rest. If this is done one can be sure that one is not missing any therapeutic opportunities. The uncertainty in diagnosis is bothersome but sometimes has to be faced. Note should be made of the fact that amebic liver abscesses occasionally break through into the pleural cavity and produce thick bloody fluid. In these cases septic fever is constant.

DIGITALIS FOR PATIENT WITH HEART BLOCK AND DECOMPENSATION

To the Editor:—Following physical and emotional strain due to the hurricane of 1938 a seventy-six year old man has been the subject of complete heart block. For the past three months he has been decompensated as evidenced by dyspnea, orthopnea, pulmonary congestion and dependent edema of the lower extremities. For the past three weeks he has been under my care. Prior to that time he was not only advised, but warned, never to take digitalis. I personally feel that with decompensated complete heart block he should be taking digitalis. For the past three weeks his pulse rate has been 36 to 39. Blood pressure is 180/80. He is now receiving 1.5 cc. of mercupurin intravenously twice a week and this has relieved his pulmonary congestion considerably, but not his dependent edema. Fluids and salt have been restricted. Should digitalis be used in this case and, if so, what would be the dangers attending its use, how would one avoid overdosage without being able to note changes in pulse rate, would periodic electrocardiographic checkups be necessary? Edward Gliserman, M.D., Niantic, Connecticut.

ANSWER.—The presence of complete heart block without Adams-Stokes attacks is not a contraindication to the use of digitalis when it is needed in the treatment of congestive heart failure, as it is in the case described. In the past, all sorts of other contraindications to the use of digitalis have also been held and one by one dispelled. These have included hypertension, aortic regurgitation and alternation of the pulse.

There should be no variation from the usual method of digitalization except for a little closer watch of pulse rate and symptoms. Although it is possible to depress the ventricular pacemaker to a low level by digitalis, this does not usually happen. It is persons with partial auriculoventricular block and Adams-Stokes attacks who must be watched particularly, rather than those with well established complete heart block. Occasional electrocardiograms are, however, desirable, although not absolutely essential, preferably three, namely just prior to digitalization, toward the end of digitalization and a few weeks later.

REACTIONS FROM AMINOPHYLLINE INTRAVENOUSLY

To the Editor:—Susan C. Dees of Duke University (*J. Allergy* 14:492, 1943) mentioned any degree of right sided cardiac failure as a contraindication to intravenous use of aminophylline, reactions having been caused by its use. Could you explain why such is the case and its possible mechanism?

Lawrence H. Hoffman, M.D., San Francisco.

ANSWER.—The reason that right sided cardiac failure represents a contraindication to intravenously administered aminophylline is not clear, since the drug has been widely employed, both orally and intravenously, as a diuretic in congestive heart failure. A detailed report of these reactions, of which several were fatal, is being prepared by Dr. James Hendrix and may be expected to help explain the mechanism.

Severe and occasionally fatal reactions have occurred with the use of intravenous aminophylline in other types of heart disease and in uncomplicated asthma. The majority of the fatal cases, however, have been associated with serious heart disease. In these instances the aminophylline was apparently diluted and administered slowly with the usual precautions.

The rapidity of the reaction in some cases with respiratory and cardiac arrest might suggest a central origin.

ANOPHELINE MOSQUITO ONLY VECTOR FOR MALARIA

To the Editor:—Has any work been done in determining the fate of *Plasmodium vivax*, *Plasmodium falciparum* or *Plasmodium malariae* when ingested by any mosquito or insect other than *Anopheles*?

Captain, M. C., A. U. S.

ANSWER.—Much work has been done in determining whether mosquitoes other than *Anopheles*, or various blood sucking insects, could transmit human malaria. In every instance the results have been uniformly negative. As malaria occurs only in association with different species of *Anopheles* mosquitoes, and since the prevalence of the disease can be definitely correlated with the efficiency or number of *Anopheles* vectors, it is extremely unlikely that any other species of insects can transmit the disease.

THE RICKETTSIAL DISEASES

R. E. DYER, M.D.

Director, National Institute of Health, U. S. Public Health Service
BETHESDA, MD.

Rickettsias are gram negative micro-organisms, coccoid or bacillary in form, found typically in arthropods. Those known to be pathogenic for man occur intracellularly in the tissues of their animal and arthropod hosts. These organisms have never been cultivated on artificial mediums free from living cells, but they grow and multiply in the various tissue culture mediums. With the exception of the rickettsia of Q fever, they do not pass filters that retain pathogenic bacteria. Several species that are not known to be associated with any disease of man or other animal have been described and named, and one species has been described that is pathogenic for lower animals but not, apparently, for man—this is *Rickettsia ruminantium*, the causative agent of "heart water disease" of sheep, goats and cattle; the identification of these organisms is based on appearance, staining reactions and occurrence in arthropods. Bodies resembling rickettsias have been isolated from cases of trachoma and psittacosis, and while there is not at the present time conclusive evidence on which to base the classification it is possible that further knowledge may place these bodies in the class Rickettsia.

The diseases of man with which species of Rickettsia are associated and of which the epidemiologic character is determined by the life cycles and the feeding habits of the arthropod vectors may be divided into four subdivisions: typhus, Rocky Mountain spotted fever, tsutsugamushi and Q fever. Q fever stands a little apart, differing somewhat from the other rickettsial diseases clinically and in the fact that the organisms readily pass through bacterial filters which retain the other strains of pathogenic rickettsias. Trench fever has often been classified as a rickettsial disease since it is louse borne and rickettsias have been described in lice and their feces which subsequently have infected volunteers. Opportunities for the careful study of trench fever have been lacking since it disappeared with the close of World War I. However, it has appeared in the European sector of the present war, and studies now in progress in Europe may clear up its relationship to rickettsias.

A characteristic of this group of diseases with the exception of Q fever is the production in patients of agglutinins for the X strains of *Bacillus proteus* (*Proteus vulgaris*). This agglutination of *B. proteus* X (Weil-Felix reaction) has been of great assistance in distinguishing the tsutsugamushi group from the typhus and spotted fever groups, since with tsutsugamushi agglutinins for the OXK strain of *B. proteus* are typi-

cally produced while the serums of patients with typhus and spotted fever agglutinate the OX₁₉ and OX₂ strains. No strain of *B. proteus* has been found which is agglutinated by Q fever serums, and the production of agglutinins in trench fever is as yet unknown. There are definite immunologic differences, illustrated by absence of cross immunity, which separate the subdivisions of the rickettsial infections.

Clinically the typhus, spotted fever and tsutsugamushi groups are characterized by sudden onset, rash, fever of fairly well defined duration, mental disturbance and pronounced prostration.

The typhus subdivision of the rickettsial infections comprises the epidemic or louse borne type and the endemic, murine or flea borne type. The Rocky Mountain spotted fever subdivision is not so clearly delineated as yet but includes in addition to Rocky Mountain spotted fever other identical or similar tick borne diseases, such as boutonneuse fever, the misnamed São Paulo exanthematic typhus, Tobia fever of Colombia, Kenya typhus and possibly the so-called tick typhus of India and South African tick bite fever. The tsutsugamushi subdivision embraces, in addition to the type disease, the disease known as scrub typhus and other of the mite borne diseases of southern Asia and the islands of the Southwest Pacific.

Of the rickettsial diseases typhus is of greatest military importance. The Rocky Mountain spotted fever group is apparently not of much military significance, although cases have occurred in military personnel and the tsutsugamushi group is occurring to some extent among our troops in the southwest Pacific zone.

EPIDEMIC TYPHUS

Synonyms.—Spotted typhus, petechial fever, jail fever, ship fever, camp fever, typhus exanthematicus, fleckfieber (German), el tabardillo (Spanish), typho-
esantematico (Italian).

Epidemic typhus is an acute infectious disease caused by *Rickettsia prowazeki*. The disease is characterized by a fairly sudden onset and a continuous fever of about two weeks terminating by crisis or rapid lysis. The most distinctive feature is a macular rash, which appears usually on the fifth or the sixth day. Persons of all ages and both sexes are susceptible.

History and Distribution.—Typhus has been one of the great pestilences of history. The earlier accounts of epidemics of diseases are not definite enough to allow the sure identification of any as typhus, but there is little doubt that, in 1489, 17,000 of the soldiers besieging Granada died of typhus. In the succeeding century a petechial fever, probably typhus, within a span of four years (1550-1554) destroyed 100,000 people in Tuscany. During the Thirty Years' War, 1619-1648, typhus repeatedly ravaged Europe. The disease appeared often in England and Ireland in the seventeenth, eighteenth and nineteenth centuries, Ireland

becoming one of the principal endemic centers of the disease. The French Revolution, the Napoleonic wars, the Crimean War and the World War of 1914-1918 were all marked by typhus. At the close of the World War the disease was prevalent in Poland, Russia and Rumania, causing close to a million deaths in the last country. The estimates of typhus cases and deaths in Russia between 1919 and 1923 run into millions.

In the Western Hemisphere epidemic typhus appeared in Mexico shortly after the Spanish conquest. It appeared in South America following the Spanish conquest of Peru, and in the highlands of Central and South America it has since remained endemic. Typhus was brought to Canada in 1659 and several times in the eighteenth and nineteenth centuries. One of the first years of Irish immigration in great numbers into Canada was 1847. Ireland, as previously mentioned, being one of the endemic foci of the disease. Of 84,445 persons immigrating into Canada that year, 75,540 were Irish. Among these there were 30,265 who sickened with typhus; 5,293 died at sea, 8,012 at Quebec and 7,000 at Montreal, making a total of 20,305 deaths. Typhus was introduced also into the various seaports of the United States at various times during the eighteenth and nineteenth centuries. This form of typhus (louse borne) has never established an endemic focus in this country or in Canada. It is noteworthy that our Civil War is one of the few wars of any magnitude in which cases of typhus did not appear in great numbers.

At the present time epidemic typhus has definite endemic foci in the highlands of Central and South America, North Africa and some parts of Central and South Africa, in Spain, in parts of France and Germany and in the invaded states of East Europe, in Russia, Turkey, Iran and Iraq, in Afghanistan and in China. There has been a definite increase in epidemic typhus in the European and North African zones since the inception of the present war.

Transmission.—Epidemic typhus is transmitted from person to person by body lice. Rickettsias are present in the feces of typhus infected lice in great numbers, and it is probable that from deposits of such feces they gain entrance to the body through abrasions in the skin. The high morbidity rate among doctors and nurses in epidemics of typhus, coupled with the fact that as a group such persons are surrounded by careful precautions with regard to protection against lice, suggests that actual contact with lice may not always be necessary. It has been shown that rickettsias remain viable and retain their virulence for many days when in dried feces of lice, and since laboratory animals can readily be infected by intranasal inoculation and since the disease has developed in laboratory workers presumably after inhalation of infectious material it seems possible that the inhalation of dried infected louse feces or the deposition of air borne infected material on the mucous membranes may be responsible for some cases.

Epidemiology.—The chief epidemiologic characteristics of epidemic typhus are as follows:

1. It occurs among populations disorganized by war, famine and social revolution.
2. It occurs first and most commonly in the poorer sections of cities, in concentration camps and in prisons.
3. It is readily transmissible from person to person through the agency of the body louse.
4. It is associated with lousiness.
5. The peak of prevalence is in the winter and spring.

There is no difference in susceptibility conferred by sex. One attack usually confers immunity which may not be permanent. There is some evidence to indicate that the more severe the attack the more lasting is the subsequent immunity.

Clinical Features.—The incubation period falls between five and fifteen days; the usual time is eight to twelve days. The onset may be preceded by one or two days in which the patient experiences malaise, headache, loss of appetite and at times nausea. In the majority of cases the disease begins abruptly with rapidly rising fever, repeated chills (not often severe) and headache.

The fever rises steadily during succeeding days, usually reaching its maximum by the end of the first week. Morning remissions of fever occur. These remissions may be slight during the second week. The fever falls usually by rapid lysis after about fourteen days, patients with uncomplicated typhus ordinarily being afebrile by the sixteenth day after the onset.

Headache is a prominent symptom, being severe and difficult to relieve. It often persists throughout the illness and may be the chief symptom complained of by the patient. Prostration and signs of cardiac weakness may be evident from the onset, usually becoming pronounced by the second week of the illness. Constipation may be troublesome throughout the illness. The general features of prostration tending toward stupor and delirium become more grave in the second week. In severe disease with definite cardiac weakness there is a tendency toward development of gangrene of the extremities, more frequently of the toes. Mental disturbance is common. This may vary from confusion, disorientation, restlessness, insomnia and irritability to delirium. Generalized aching and soreness of the eye muscles are often present. Nosebleed sometimes occurs.

In cases of severe involvement which end in recovery there is often a sharp change toward the end of the second week. If the disease is uncomplicated the temperature falls and the stuporous condition disappears about the fourteenth day. Prostration and cardiac weakness continue for a varying length of time after defervescence, depending to a great extent on the age of the patient, those in the lower age groups recovering more quickly. In cases which proceed to a fatal outcome the prostration and the mental cloudiness increase, and coma occurs.

Some evidence of involvement of the respiratory system is usually present. This varies from a mild cough, which may never be troublesome, to definite bronchopneumonia.

The most characteristic feature of the disease is a rash which appears on the fourth to sixth day after onset of the illness. Rarely it may appear as early as the third or as late as the ninth day. The rash consists of rose red macules and papules. These lesions at first disappear on pressure but rapidly become petechial and darker as the disease progresses. In severe involvement coalescence of the lesions occurs. The eruption appears first on the inside surfaces of the upper arms or on the sides of the chest and the upper part of the abdomen and spreads to the rest of the chest, the back, the arms and the legs, usually being less pronounced on the extremities. The palms and the soles may be involved, while the neck and face are seldom included in the area of distribution. The

rash becomes brownish as recovery ensues, usually disappearing during defervescence. In some cases the remnants of the rash may be discernible for several weeks.

The pulse rate often remains below 120 or even 100. A rate of over 130 indicates severe involvement with a doubtful prognosis. Not uncommonly there is a drop to a rate lower than normal (50 to 60) during convalescence, the pulse gradually regaining the normal rate as strength returns. On recovery from a severe attack, shortness of breath may be noticeable for several weeks. Recovery once assured is usually complete and sequelae are absent.

The fatality rate varies from 20 to 60 per cent in different epidemics. In the same epidemic the rate may be below 5 per cent in children and over 80 per cent in those over 50 years of age. In sporadic cases in interepidemic periods the rate is much lower.

Complications.—Among the complications which may be encountered are bronchopneumonia, parotitis, otitis media, mastoiditis and thrombosis of various veins.

Laboratory Findings.—In many instances albuminuria is present at the height of the illness. It clears with convalescence.

Cytologic examination of the blood shows nothing characteristic. The white cell count varies from one indicating moderate leukopenia to one of about 12,000, with occasional uncomplicated cases showing as many as 15,000 white cells per cubic millimeter.

The Weil-Felix reaction usually becomes positive during the second week of illness, reaches its height about the time convalescence is established and disappears rather rapidly. It is advisable to test at least two samples of serum, one taken early in the illness and a second late in the second week. With a sensitive antigen the serums of patients with typhus often reach a titer between 1:10,000 and 1:100,000. The OX₁₉ strain of *B. proteus* is more commonly agglutinated than OX₂ and is the strain customarily employed. The serums of patients with Rocky Mountain spotted fever also show the Weil-Felix reaction in high titers and consequently this reaction is of no practical value in differentiating between the two diseases. Serums from persons suffering from other illnesses not related to the rickettsial diseases may show the Weil-Felix reaction in dilutions as high as 1:320 and occasionally 1:640.

Recently it has been found that complement fixation can be utilized in the diagnosis of typhus. This test, with typhus rickettsias used as an antigen, becomes positive during the second week of the disease and may remain positive for many years. It is of value in differentiating typhus from Rocky Mountain spotted fever.

Pathology.—Grossly there is little else than the partially faded exanthem, moderate splenic enlargement and the frequent presence of complicating bronchopneumonia. The essential lesion is focal injury of capillary and precapillary vessels, characterized by endothelial swelling, proliferation and necrosis with thrombosis and by nodular perivascular exudation of lymphocytes, plasma cells and monocytes. Such lesions are most frequent in the skin, heart, great vessels, kidneys, adrenal glands, testes, epididymides and especially the brain, the cerebral cortex being usually the most involved. Very characteristic are small paracapillary nodes of microglia. Splenic hemorrhages, erythrophagia, plasma cell infiltration and infrequent thrombi are reported.

Treatment.—There is no specific treatment of established value. Convalescent human serums and serums from horses inoculated with rickettsias have been tried without convincing results. A hyperimmune rabbit serum has been described, and early results in a small series of cases indicate that it may be of therapeutic value. Many of the newer therapeutic chemicals have been tried, with little evidence of any value and some evidence of harm.

Good nursing with every care to maintain the strength of the patient is of the greatest importance. Cardiac depressants should be avoided. For the relief of the headache, acetylsalicylic acid may suffice; otherwise codeine or morphine may be necessary. Digitalis may be given with possible benefit to patients showing signs of cardiac failure. Constipation is best controlled by means of enemas or with mild laxatives. Care should be exercised to prevent bed sores. The patients, particularly those in the older age groups, should be confined to bed until convalescence is well established.

Prevention.—The prevention of epidemic typhus rests on the control of lice. All patients and their contacts must be completely freed of lice, and all persons coming from typhus-infected areas should be treated as contacts. The body louse nests in the clothing and usually remains there when the clothes are removed. Clothing may be disinfected by several methods using heat or pediculicide powders¹ and chemicals. The louse infested person should be bathed and the hair of the head and the body clipped. Those in attendance on patients (e. g. doctors, nurses and orderlies) should be provided with louse proof clothing made of white material and fashioned as coveralls with the openings at the wrist, ankle and neck closely fitted. Stockings should be drawn up over the bottoms of the coveralls and rubber gloves pulled over the wrists. Care should be taken in the examination of patients since there is some evidence that inhalation of the dried excreta of infected lice may be responsible for some secondary infections.

Vaccines of various types have been prepared for immunization against typhus. Attenuation of the living rickettsias by heat or by addition of such substances as bile, as well as partial neutralization by convalescent serum, has been used. However, the dangers inherent in the use of a vaccine containing living rickettsias as shown by the fact that attacks of the disease have been produced by inoculation with such vaccines should prohibit their use. Several preparations have been made which utilize rickettsias killed usually by solution of formaldehyde or phenol. One of them, that of Weigl, apparently gives good immunity, but unfortunately it cannot be produced on any very large scale, as its production requires that a suspension of rickettsias be injected into the rectums of lice, that the lice be subsequently fed on typhus immune persons and that the louse intestine be then removed and prepared as a treated suspension, which is used as the vaccine. Approximately one to two hundred lice are needed for the vaccination of a single person. A second source of rickettsias for the preparation of vaccine of killed organisms is the yolk sac of the developing chick embryo after its inoculation with typhus rickettsias. Vaccines made from killed rickettsias secured from the lungs of intranasally infected mice, rats or rabbits have also been prepared.

1. Evidence is accumulating that body lice can be controlled by the use of pediculicide powder alone.

The vaccines of killed rickettsias at present in use give good results when tested in animals, but no adequate field tests in the presence of epidemic typhus have as yet been made. Typhus has occurred in a number of laboratory workers who had previously received such vaccines and apparently was modified in severity, most of these workers showing very mild symptoms of only a few days duration. The length of time for which a vaccine may be expected to give its full protection is not known, but evidence at hand indicates that after the initial series of three injections a "booster" dose should be given every few months when the danger of typhus is present.

ENDEMIC TYPHUS

The difference between the epidemic form of typhus and the endemic or murine type is largely epidemiologic, with some variations, not entirely explained, in the immunologic observations and in the reactions produced by the infection in laboratory animals.

The causative organism of endemic typhus has been named *Rickettsia mooseri*, and the disease is also referred to as murine typhus and as Brill's disease.

History and Distribution.—Mild typhus was first reported in the United States in New York in 1898. In the next few years it was reported in additional communities—Atlanta, Ga., 1913; Charlotte, N. C., 1914; Galveston, Texas, 1916; Alabama, 1923, and others. The epidemiologic features indicated common rats as a reservoir, and typhus infected rat fleas and infected rats have been found many times in nature in foci where the disease was occurring in man.

In 1929 the human cases of endemic or murine typhus were practically limited to the towns, particularly those along the southern Atlantic coast from Baltimore south and continuing along the Gulf coast and up the Rio Grande River as far as El Paso, Texas, with a few cases in southern California. Towns in the interior of the Southern states were likewise affected but to a lesser extent as the distance from the seaboards increased. As late as 1932 the northern limit of the disease in Alabama was about in a line with Montgomery. Since 1932 cases have appeared farther north until at present the known northern limit of the disease has reached central Tennessee, with additional foci in Cleveland and Cincinnati and in Washington, D. C.

Since the identification of this form of typhus in the United States it has been found to be widespread over the world, especially along the sea coasts. It is probable that endemic typhus occurs at the inception of and during louse borne epidemics but is not recognized as such.

Transmission.—There is a reservoir of the infection in nature in the common rat and possibly in other rodents. Evidence indicates that the rickettsias are transmitted from rat to rat by rat fleas and rat lice. They have not been demonstrated in the salivary glands of the flea, and experiments to determine the transmission of this form of typhus by the bite of the flea alone have been unsuccessful. Transmission to man most probably occurs through the medium of the infected feces of rat fleas.

Epidemiology.—The chief epidemiologic characteristics of endemic typhus are as follows:

1. Human cases are associated with rat harbors.
2. The disease occurs most commonly among workers in food handling establishments.

3. There is no predominance of cases among the poorer sections of the population.

4. Transmission from person to person through contact or by rat fleas has not been observed.

5. The peak of prevalence is in late summer and fall.

Clinical Features.—The clinical features of the endemic form of typhus are identical with those of the epidemic form described earlier with the exception that in the average case they are much less severe than those in the majority of cases of epidemic typhus. The rash in endemic typhus does not often appear before the fifth day and may comprise only a few macules which may disappear in a day or so. The general symptoms are on the average much milder. The case fatality rate is below 5 per cent, with most of the deaths occurring in patients over 45 years of age.

The fact that the case fatality rate is much lower in murine typhus than in epidemic typhus has usually been considered to be due to a difference in the virulence of the flea borne as compared with the louse borne strains. It should be noted, however, that murine typhus occurs among populations in which the element of human distress is lacking, in contrast to the great epidemics of louse borne typhus which appear among the most miserable populations in time of war, economic depression, starvation, overcrowding and lack of heat. Murine typhus occurring under such conditions might possibly be a more severe disease. This question, together with that of the interrelationship of the two types of disease, remains to be answered.

The laboratory findings are similar to those noted for epidemic typhus except that leukopenia is more common. The Weil-Felix reaction is also positive in high titers.

When typhus is present as an epidemic, little difficulty should be experienced in making the diagnosis. Sporadic cases whether of the epidemic or of the endemic form of the disease give more difficulty. This is true particularly in those sections where cases of Rocky Mountain spotted fever or of tsutsugamushi may be encountered also. It is practically impossible to make a differential diagnosis prior to the appearance of the rash. Other diseases with which typhus has at times been confused are measles, meningococcemia and typhoid. Drug rashes also may be confusing.

Prevention.—The control of endemic typhus from present knowledge should be based on control of the rat population—by trapping, poisoning and rat proofing. The last of these measures is the only one that may be considered as of permanent value. Trapping and poisoning must be continuous to be of any practical value and must be supplemented with an attack on the rat's home and his sources of food by rat proof construction.

Vaccines are prepared against endemic typhus by the technics employed in the production of those for epidemic typhus. They have been shown to have good protective value in animals but have not been tested adequately in human beings.

ROCKY MOUNTAIN SPOTTED FEVER

The causative agent is *Rickettsia rickettsii* (*Derma-centroxenus rickettsii*).

History and Distribution.—As the name implies, Rocky Mountain spotted fever was first recognized in the Rocky Mountain section of the United States,

where it has been extensively studied since 1902. Until 1930 the disease was thought to be confined to eleven states of the Northwest although a case in Indiana had been reported in the literature and the diagnosis of spotted fever had been considered on occasion in other states prior to 1930. A recent review of clinical records shows that the disease was present in certain sections of the East at least as early as 1912. During the spring and early summer of 1930 the disease was clinically identified and the virus isolated in suspected cases occurring in the Eastern states. Since the time of definite identification of the disease in states outside the originally known area, new states or countries have been added to the known regions of distribution each year. At present study of suspected cases has shown that the area of distribution includes forty-one states. Five of the New England states—Maine, New Hampshire, Vermont, Connecticut and Rhode Island—have not as yet reported confirmed cases known to have originated in those states. In the Middle West, cases have not been identified in Wisconsin and Michigan. The number of cases reported each year in the United States has remained fairly constant: 560 in 1939, 457 in 1940, 516 in 1941. Rocky Mountain spotted fever is present in two provinces of western Canada and in two states of Brazil. In the latter country the disease has been named exanthematic typhus of São Paulo. It has been identified in Colombia, where it was originally described as Tobia fever.

Transmission.—Several species of ticks are known to be capable of transmitting Rocky Mountain spotted fever. *Amblyomma cajennense*, *Dermacentor parumapterus marginatus*, *Dermacentor occidentalis*, *Rhipicephalus sanguineus* and *Dermacentor albipictus* have been shown to be efficient transmitting agents under experimental conditions. However, the dog tick (*Dermacentor variabilis*), its near relative the wood tick of the Northwest (*Dermacentor andersoni*) and *Amblyomma americanum* are the only species biting man in which the virus of the disease has been found naturally present in the United States. *Amblyomma cajennense* is the common vector in Brazil. The rabbit tick (*Haemaphysalis leporis palustris*) has been found naturally infected, but this species does not bite man; it may, however, play an important part in preserving and spreading the virus in nature. There is no evidence at present to indicate that any arthropod other than the tick transmits the disease.

Clinical Features.—In many of its general aspects this disease resembles typhus, the chief differential points being the duration of fever and the time of appearance and the location of the rash.

In man the disease has an incubation period of two to twelve days, being most often a week or a little less. As in typhus, the actual onset may be preceded by a few days of ill defined prodromes—loss of appetite, listlessness and headache. The onset is usually sudden, with a chill or chilly sensations and rapidly rising fever. Prostration is usually pronounced. In the more severe type of the disease nosebleed may occur early. Soreness of the muscles and the joints is commonly present. The temperature rises rapidly, reaching its highest point usually in the second week. Morning remissions of 1 to 3 degrees F. occur. The termination of fever is by rapid lysis occurring usually about the twenty-first day, although patients with mild disease may be afebrile before the end of the second week.

The most distinguishing characteristic of the disease is the rash. This appears between the second and fifth days, usually on the third or the fourth. The typical rash may be preceded by a suggestive mottling of the skin, and this may easily be confused with the early rash of measles. The early rash usually disappears in a few hours to be followed by the typical maculopapular lesions. The lesions are rose red at first and become fainter, almost disappearing during the morning remissions of fever early in the disease. They become more distinct each day until they are definitely petechial in all but the mildest forms of infection. In severe involvement the spots become deep red or purplish and confluent. Necroses may develop. The rash usually persists throughout the febrile period and into convalescence, becoming brownish. Often a branny desquamation occurs over the areas where the rash was thickest. The site of first appearance and the spread and final distribution of the rash are important in the diagnosis of the disease. Usually the rash appears first on the wrists and the ankles, spreading rapidly in the first twenty-four to forty-eight hours to the back, then to the arms, the legs and the chest, and last to the abdomen, where it is least pronounced. The palms and the soles are frequently involved, often the face and occasionally even the scalp.

Nervous and mental symptoms are common: restlessness, insomnia, disorientation and in severe cases delirium. In fatal cases coma usually precedes death, which occurs about the end of the second week.

Convalescence of patients with severe involvement is apt to be slow and may be complicated by visual disturbances, deafness or mental confusion. Although recovery may be delayed, it is usually complete in the end. The case fatality rate, as in typhus, varies directly with age. The crude rate for reported cases in the United States is 18.4 per cent.

Laboratory Findings.—The white cell count is increased in cases of Rocky Mountain spotted fever, usually being about 12,000, although it may be as high as 30,000, which is in contrast to the count suggesting moderate leukopenia or the normal one usually seen in cases of typhus.

The Weil-Felix reaction gives no aid in differentiating spotted fever from typhus. In a large number of cases it has been noted that agglutinins for *B. proteus* OX₂ occur more frequently in the serums of patients with spotted fever than in those of patients with typhus, but since they do occur in some of the latter the stated difference is of no help in the individual case. When agglutinins for both strains are present, those for OX₁₀ are usually higher than those for OX₂. The agglutinins for OX₁₀ usually appear toward the end of the second week of the disease. At times they are delayed until early convalescence. In some proved cases of spotted fever no agglutinins for *B. proteus* X were produced. The curve of agglutinins in its rise and fall is similar to that seen in typhus. As in typhus, it has been found that complement fixation with the rickettsias of spotted fever used as an antigen becomes positive in the second week of illness.

Pathology.—Histologic changes in the brains of infected guinea pigs do not vary appreciably from those already described for typhus as far as the character of the individual lesions is concerned. It has been shown, however, that a higher proportion of the focal lesions

is found in the midbrain, pons, medulla and cerebellum in spotted fever than in typhus.

Treatment.—As with the other rickettsial diseases, there is no specific treatment of proved value. Injections of serum from convalescent patients have been tried repeatedly, as have transfusions from immune donors, but without definite benefit. A hyperimmune rabbit serum has recently been developed which has definite therapeutic value in the treatment of animals that are ill with spotted fever. A small series of patients has been treated with this serum with results indicating that this means of treatment will effect a reduction of the case fatality rate if the serum is administered before the third day of the rash. A definite opinion of its value should be withheld until additional observations have been reported. The newer chemicals—metaphen, sulfanilamide and sulfapyridine—have been tried clinically without definite evidence of benefit to the patient. The experimental use of sulfanilamide and sulfapyridine in the treatment of spotted fever in guinea pigs increases both the severity of the infection and the death rate.

Good nursing care, avoidance of exertion, mental or physical, maintenance of the fluid intake, by mouth preferably, by rectal drip or hypodermoclysis if necessary, and relief of the headache with acetylsalicylic acid, codeine or morphine give the best results. The mind of the physician may be relieved by the knowledge that there is more danger from overtreatment of these patients than from undertreatment.

In fatal cases death usually occurs before the fifteenth day, commonly between the eighth and the twelfth day. If the patient is going to recover, some indication of this may often be found in a slight decrease of the temperature about the fourteenth or fifteenth day which becomes more definite with each succeeding day. Final defervescence occurs by rapid lysis which often brings the temperature to normal about the end of the third week. The temperature may rise above normal in the afternoons for a few days longer. If no complications are present, a slow but steady improvement may be expected. After severe infections convalescence may be prolonged for many months, and remnants of the rash may be present for several months or even years.

Prevention.—Methods for the control of spotted fever have been directed toward the eradication of ticks but have not been very successful. The difficulties of the problem may be recognized when the variety of hosts on which these parasites feed is considered. Poisoning of rodents, dipping of domestic stock, clearing away of brush and burning over of tick infested areas probably assist in the reduction of ticks, but it is only fair to state that, although such methods have been tried, there is little evidence that much has been accomplished in the way of limiting the disease. Tick repellent powders have been tried, but the practical value of those in use is limited.

Probably the most effective method of prevention is the exercise of personal care. Known infected areas should be avoided as far as possible during the tick season. Those who must visit such areas should frequently examine clothing and body for ticks. Usually the tick does not become attached to its host at once but crawls around for several hours. It has been shown also that the chance of receiving infection from the bite of an infected tick is directly proportional to

the length of time the tick has fed. Care should be taken in handling the tick when removing it from the person or from a pet. It is best to remove ticks with small forceps or with a piece of paper held in the fingers. The hands should be washed thoroughly with soap and water after handling ticks. Pets should be thoroughly deticked every few days during the tick season. There is little danger of leaving the mouth parts of the tick in the wound. The wound itself may be treated as any other abrasion, since there is nothing to distinguish the bite of an infected tick from that of a noninfected tick, nor is there any evidence that such measures as cauterization will lessen the chances of subsequent development of the disease.

A vaccine made from infected ticks for use against spotted fever was elaborated and is prepared by the United States Public Health Service at Hamilton, Mont. A second method of preparing vaccine is now in use. This method utilizes the rickettsias grown in the yolk sac of the developing chick embryo. Evidence from animal experiments indicates that the yolk sac and tick vaccines are of comparable value in prevention. Occasionally typhus occurs among those who have been vaccinated but is usually mild. The evidence as to total prevention is hard to evaluate but seems to indicate that vaccination appreciably lessens the chance of subsequent infection. There is no good evidence that the vaccine is of value after the infection has been acquired, nor is it of any value in treatment.

BOUTONNEUSE

Synonyms:—Marseilles fever; fièvre exanthématique; escarro-nodulaire.

Boutonneuse is caused by *Rickettsia conori* and is closely related to Rocky Mountain spotted fever. It has an extensive distribution in Rumania, Portugal and the countries bordering the Mediterranean. Results of investigations indicate that the so-called Kenya typhus in East Africa and South African tick fever may be closely related to boutonneuse, the former probably being identical with boutonneuse.

Transmission.—The infection is transmitted by the brown dog tick *Rhipicephalus sanguineus*. As in some other rickettsial diseases, a reservoir probably exists in nature in the lower animals. The dog apparently is an important reservoir of boutonneuse. The tick *R. sanguineus* is also capable of harboring and transmitting the rickettsias of Rocky Mountain spotted fever.

Clinical Features.—The incubation period is five to seven days, although in occasional cases it may be as long as eighteen days.

As in other rickettsial infections, the onset is usually abrupt, with fever and repeated chills or chilliness. The temperature rises rapidly and may reach 104° F. in a few hours. Headache and pain in the muscles and the joints are common complaints. Prostration is usually not a prominent feature of this disease. The febrile period is from eight to fourteen days, defervescence taking place by rapid lysis.

Insomnia is common throughout the febrile period. As the disease is seen in Marseilles and Italy, mental disturbance is less severe than in other rickettsial infections, although patients with severe involvement may show moderate delirium. The case fatality rate is low, being less than 3 per cent.

A papular or maculopapular rash appears on the second to fourth day of illness. It begins on the trunk,

legs and arms and extends rapidly over the entire body, usually appearing on the face last. The palms and the soles are commonly involved. The rash may be less pronounced on the abdomen than elsewhere. It may be found on the soft palate as small round red spots which persist only a few days.

The individual lesions comprising the rash may become hemorrhagic, especially those on the legs, but there is little tendency to coalescence. The rash usually disappears with convalescence.

Frequently a small ulcer about 2 to 5 mm. in diameter, showing a black necrotic center surrounded by a red areola, is found at the onset of illness. This has been named *tache noire* (black spot) and is similar in appearance to the ulcer often seen in *tsutsugamushi*. The *tache noire* may be found on any part of the body, usually on a part covered by clothing; this is supposed to be the site of the infecting tick bite. Sometimes the regional lymph nodes become enlarged and tender.

The Weil-Felix reaction with the OX₁₀ strain of *B. proteus* used as an antigen becomes positive late in the disease.

Treatment and Prevention.—There is no specific treatment for *boutonneuse*, and no vaccine is available at present.

The prevention lies largely in the measures advised for the prevention of Rocky Mountain spotted fever.

TSUTSUGAMUSHI

Synonyms.—Japanese river fever; kedani fever; Japanese flood fever; scrub typhus.

Tsutsugamushi is an acute febrile disease clinically resembling the other rickettsial infections. The causative organism is *Rickettsia nipponica* (*Rickettsia orientalis*, *Rickettsia tsutsugamushi*). The disease has long been recognized as prevailing in Japan along the course of rivers and has shown a tendency to increase at the time of flood conditions. Originally thought to be confined to Japan, it has been shown to be probably identical with the so-called scrub typhus of Malaya, the mite borne coastal fever of Queensland in Australia and the pseudotyphus of Sumatra. It is also present in the Philippines and probably has a fairly wide distribution throughout the other islands of the southwest Pacific.

Transmission.—*Tsutsugamushi* is transmitted to man from a reservoir probably in field mice and other rodents by the larval form of the mite *Trombicula akamushi* or *kedani* mite. In Malaya and Sumatra the transmitting mite is named *Trombicula deliensis*. The larvae of this mite do not ordinarily feed a second time, and the adults do not feed on animals. The infection contracted by larvae through feeding on infected rodents is apparently transmitted through subsequent stages of the life cycle to the larvae of the next generation.

Epidemiology.—In Japan the disease is more prevalent during the summer months, while in Malaya there is little seasonal variation. There is a greater incidence of the disease among males than among females, a fact that is explained by the occupational exposure of males in rural occupations.

Clinical Features.—The incubation period in a small series of cases was determined as seven to twenty-one days, the common period being a little less than two weeks. As in the other rickettsial diseases, prodromal

symptoms such as headache, malaise and loss of appetite may precede the onset. At the onset chills or chilliness, headache and fever occur. Deafness is not an uncommon early symptom and may persist throughout the disease. There may be pain in the joints and in the chest. Drowsiness or some other evidence of mental disturbance is often present. The fever is continuous in type with morning remissions of 1 to 3 degrees (F.). Prostration is often noted throughout the illness. In patients who are recovering the temperature usually falls to normal about the fourteenth to sixteenth day. This may be followed by a slight rise in temperature on the succeeding day or days to be followed by complete recovery. The case fatality rate for all ages is about 15 per cent. A definite increase of the rate occurs with increase of age.

The most characteristic sign consists of a small necrotic ulcer supposedly at the site of the infecting mite bite. This ulcer is 2 to 5 mm. in diameter with a black necrotic center surrounded by a red areola. Apparently it is found in the great majority of cases of *tsutsugamushi* as observed in Japan. In the disease as it occurs under the name of scrub typhus in Malaya the initial ulcer is not always present. There is general lymphadenopathy, which is especially noticeable in glands draining the site of the primary ulcer, which is usually found in the pubic region, in the axilla or on the legs.

The characteristic rash of *tsutsugamushi* appears from the fourth to the eighth day after onset and consists of macules and slightly elevated rose red or pink papules; it does not become petechial. This rash appears first on the trunk and the face and extends to the legs and the arms. It may be present on the palms and the soles, and occasionally the face and the scalp are involved. The rash reaches its height in about four days and fades within six or seven days. An enanthem may be present on the soft palate.

Many of the patients show bronchial symptoms with a dry cough; in occasional ones a mucopurulent sputum develops and pneumonia may occur as a complication.

Hyperesthesia, pains in the muscles and the joints, deafness, clouded mentality, insomnia and delirium may be encountered. A certain degree of immunity is conferred by an attack, but in some cases this lacks permanence.

The Weil-Felix reaction with the OXK strain of *B. proteus* used as an antigen is usually positive after the tenth day in dilutions of 1:160 and above, but not that with the OX₁₀ or that with the OX₂ strain. The waxing and waning of the patient's agglutinins against the OXK strain of *B. proteus* is similar to that seen in tests with strains OX₁₀ and OX₂ in cases of typhus, the peak titer being reached about the time convalescence is established. In some cases the Weil-Felix reaction may remain persistently negative. As in other rickettsial infections, it is advisable to examine one sample of serum when the disease is first suspected and a second sample near the termination of illness.

Pathology.—Microscopic examination of the brain shows the presence of lesions similar to those found in Rocky Mountain spotted fever and typhus.

Treatment.—There is no specific treatment for *tsutsugamushi*. Drugs may be used, especially to relieve headache and insomnia. As in other rickettsial diseases, cardiac depressants should be avoided. The

primary ulcer may be treated like any other similar lesion of the skin as there is no evidence that local treatment of the ulcer will influence the course of the disease once it has developed.

Prevention.—The wearing of mite proof clothing has been recommended by the Japanese for those working in mite infested regions. Since many of these areas lie in the tropics it is doubtful that this recommendation is of much practical value. Repellent powders, shown to be of value against lice, may be tried. Frequent baths may be of some value in removing mites prior to attachment for feeding. When possible the bed should be made on some structure which will remove the bedding from contact with the ground.

No vaccine has been developed against tsutsugamushi. Since there is no cross immunity between this and the other subdivisions of the rickettsial diseases, it is not to be expected that vaccines against typhus and spotted fever will be of any value against tsutsugamushi.

Q FEVER

Present knowledge of Q fever began in 1937, when human cases of this new disease entity were described in Australia and shown to be caused by an organism to which the name *Rickettsia burneti* was given. At about the same time a strain of rickettsias was isolated from ticks in Montana and named *Rickettsia diaporica*. Later work showed that these two infectious agents are identical. *R. burneti* has been isolated from ticks and from bandicoots in Australia. The rickettsia of Q fever differs from the other known pathogenic strains of rickettsias in being readily filtrable through ordinary bacterial filters. Agglutinins for the X strains of *B. proteus* do not develop in the serum of patients with this disease.

Q fever may appear in two clinical forms, one presumably transmitted by the tick and the other probably air borne from infected animals or possibly from the dried feces of infected ticks. This second form of the disease has been recognized only in accidentally infected laboratory workers.

The Australian cases have been in general confined to workers in abattoirs, to foresters and to dairy workers.

Clinically the cases reported in Australia are characterized by a fairly acute onset with chills, prostration and fever. No rash appears. Headache is pronounced in the majority of cases; sweats at night and insomnia are common. The fever is continuous in type, lasting from a few days to two to three weeks. The pulse is slow in comparison with the height of the temperature, and the white blood cells remain within normal limits. Neither symptoms nor thoracic findings in the Australian cases have suggested any important pulmonary involvement.

The disease in the laboratory workers accidentally infected, referred to in a foregoing paragraph, belonged clinically in the atypical or virus pneumonia group. In these patients two types of onset predominated, one coryza-like, the other with headache, chilly sensations and general malaise. Following the onset there was a latent period of about three days in which the patient continued to work while feeling ill. One laboratory worker had a dramatic onset with abdominal cramps, chills, fever and headache while at work.

Severe and persistent headache was an outstanding symptom developing during the latent period. Other

complaints on admission to the hospital were chills, fever, sweats and generalized body aches and pains. A few of the patients had experienced some nausea and vomiting earlier. A short hacking cough developed in several of the patients. In only a few was this cough productive, with a small amount of thick tenacious white mucus. In none of the cases was there observed a "prune juice," "rusty" or blood tinged sputum. In approximately half of the cases vague pains developed in the substernal region or on the side of the demonstrated pulmonary lesion. The pain in the chest had more the character of neuralgia than of pleurisy, as it was not associated with respiration. All the patients complained of insomnia.

Roentgen examination of the chest gave the most typical and consistent evidence of pulmonary lesions. Soft, infiltrative lesions, single or multiple, were visible on the films but were not of the uniform density seen in lobar pneumonia, these lesions appearing to be more of the patchy type observed in bronchopneumonia. The roentgenologist reported the films as revealing early pneumonia or pneumonitis.

Physical signs of pulmonary involvement were minimal. A slight dullness to the percussion note, a slight increase in breath sounds of a bronchovesicular character and an occasional moist rale over the involved area were the most that usually could be elicited. It is doubtful if without roentgen examination many of these patients would have been seriously considered to have had a pneumonic process.

Although the disease in these cases closely followed the picture presented by the so-called atypical pneumonias, efforts to isolate *R. burneti* from other atypical pneumonias has so far resulted in failure.

Treatment is symptomatic.

The case fatality rate in both forms of Q fever is practically zero. The disability lasts from ten days to three or four weeks.

TRENCH FEVER

Trench fever, also known as five day fever and Wolhynian fever, is a febrile disease transmitted to man by the body louse. Extracellular rickettsias have been found in lice fed on patients with the disease and are present in the feces of such lice. Trench fever disappeared after World War I and opportunity was not present for intensive study until its recurrence with the present war. As a result its true relationship to the other rickettsial infections is not yet known.

The incubation period varies from five to twenty days. The onset is sudden with headache and pain in the legs, most noticeable in the shins. There is a sharp rise in the temperature which may endure for about five days to one week, to be followed by a normal temperature. Relapses are frequent, three or four recurrent bouts of fever being common.

A rash is present in the majority of cases, being usually macular, with occasional cases showing papules. This rash may occur as early as the second day of the initial attack of fever or during one of the relapses. It is most commonly observed on the trunk and may disappear in twenty-four hours.

There is no report of agglutination of any of the X strains of *B. proteus* by serums from patients.

The death rate is nil.

There is no specific treatment for this disease and no vaccine. Prevention, as in epidemic typhus, consists in the eradication of body lice.

THE ACUTE DIARRHEAL DISEASES

ALBERT V. HARDY, M.D.

AND

JAMES WATT, M.D.

BETHESDA, MD.

Historically the diarrheal diseases have been a plague of armies, a major hazard to the life and health of infants and a common cause of illness among institutional inmates. The expanded sphere of our nation's activity now includes areas where these disorders still remain in their historical place of importance. Thus American physicians and health authorities face the acute diarrheal diseases not as a fast disappearing group of disorders but as a major current medical problem.

During the past six years the National Institute of Health has maintained a field laboratory for the investigation of these diseases. Studies have been conducted in four widely differing areas selected as representative of those with very high, high, medium and low mortality from diarrheal diseases (Puerto Rico, New Mexico, Georgia and New York City). As a part of this work we studied 1,499 cases occurring in the general population, obtained satisfactory clinical data on 1,247 of these and recorded epidemiologic histories on 830 households. A total of 8,643 survey fecal cultures were obtained on representative persons. Institutional inmates, among whom clinical disease and subclinical infection were relatively common, have been studied extensively, and some observations were obtained on military groups in which diarrheal disease was troublesome. New, highly selective culture mediums were used which increased the reliability of bacteriologic findings.

ETIOLOGY

A clinical and etiologic classification of the diarrheal diseases is given in table 1. Primary infectious diarrhea is caused by pathogens which establish themselves and grow in the enteric tract. Various organisms are known to be responsible, and others are held under suspicion. In parenteral and secondary diarrhea the gastrointestinal disturbance is but one part of a symptom complex. The genesis of the diarrhea that frequently occurs in acute infectious diseases, in paranasal sinusitis and in some other localized infections is not clearly known.

Acute noninfectious diarrhea is commonly caused by the ingestion of toxic or irritating substances. The offending material is usually food in which staphylococci or other organisms have grown. Water heavily polluted with bacterial decomposition products or industrial wastes is involved less frequently. Allergic and neuropsychiatric disorders as well as nutritional deficiencies may cause episodes of diarrhea, usually chronic in form. The popularly incriminated "dietary indiscretion" is blamed rightly in some cases. Various chemical compounds, including cathartics, also may give a noninfectious diarrhea.

A classification of "cause unknown" has weight only following adequate study by competent observers. Some cases may be differentiated as instances of infectious or of noninfectious diarrhea through their clinical and epidemiologic characteristics.

Having in mind the causes of diarrhea, the first problem in an etiologic study is to determine the relative importance of each. In this report we limit attention to the acute diarrheal diseases. Cholera with its distinctive clinical features and limited geographic distribution will not be considered.

The proportion of patients with endemic diarrheal disease whose stools were found culturally positive for *Shigella* in our study is given in table 2. The findings in New Mexico and Georgia were similar, and the data from these states are shown combined. The stools of the patients were examined culturally at least once during the acute phase of the disease. The fecal specimens from 76 per cent of those with severe and 58 per cent of those with milder disease were culturally positive for *Shigella*. There was an increase in the proportion of those with positive fecal cultures as the number of examinations during illness increased—from 62 per cent of those with severe disease who had one examination to 90 per cent of those with more than three examinations. The stools of a few of the New York City patients were examined late in the illness, but all the patients are included. The proportion whose disease was found due to *Shigella* was less than in New Mexico and Georgia.

The percentage with positive findings was lowest for the group whose ages were under 6 months, but the percentage varied widely with area and with severity of illness. In New Mexico and Georgia 63 per cent of the infants under 6 months with severe diarrheal disease had cultures positive for *Shigella*; 33 per cent of those with mild intestinal disorder had positive cultures. In New York only 7 per cent of the 57 patients under 6 months were found to have positive cultures. Corresponding variations, though less pronounced, are apparent in the groups with ages from 6 to 12 months and at one year. In older age groups the percentage with positive findings was high in all three areas.

The cultural findings for institutional inmates were of a similar nature. At a hospital for patients with mental diseases in Puerto Rico, for example, 149 (75 per cent) of a total of 198 patients reported as having diarrhea were found to have fecal cultures positive for *Shigella*.

Each clinical case of acute diarrhea observed in New Mexico during the first two years of our study was examined by an experienced protozoologist (the late Bertha Kaplan Spector), but in spite of a carrier rate of 19.4 per cent a diagnosis of amebic dysentery was confirmed in only 1 case, whereas the common occurrence of bacillary dysentery was readily established.

Salmonella was rarely isolated from persons with endemic disease.¹ This is in sharp contrast to observations reported from South America.² Workers in Montevideo, Uruguay, studied bacteriologically 395 infants and children hospitalized for "enteritis." They isolated *Salmonella* from 126 (32 per cent) and *Shigella* from 80 (20 per cent).

Various strains of paracolon bacilli, of *Pseudomonas* (e. g. *Bacillus pyocyaneus*) and of *Proteus* were isolated from patients whose stools were otherwise culturally negative. They were also found in the stools of healthy persons. Our data did not establish or

1. In a study now in progress in New Orleans these organisms have been isolated from more than 10 per cent of the children hospitalized for diarrheal disorders.

This paper, in a symposium on "Tropical Diseases," is published under the auspices of the Section on Practice of Medicine.

disprove the etiologic role of these organisms. Parasitologic examinations were obtained in the New Mexico cases. Intestinal parasites did not appear to be responsible for any of these.

Parenteral infection was of minor importance as a cause of acute diarrhea in New Mexico, Georgia and Puerto Rico; it was believed responsible in a relatively high proportion of the cases in which the stools were culturally negative in New York.

groups and 10 among the inmates of hospitals for patients with mental diseases) were nonexplosive in character. All these were found due to some variety of *S. paradysenteriae*. There were 9 explosive epidemics. One of these was due to *Shigella* and another to *Salmonella typhi* murium. In 7 the stools of all persons examined were culturally negative for these organisms and the outbreaks had the clinical and epidemiologic features of "food poisoning."

TABLE 1.—A Clinical and Etiologic Classification of Diarrheal Diseases

Group	Clinical Entities	Usual Course	Severity	Etiologic Agent
Primary infectious diarrhea	Bacillary dysentery	Acute	Mild to very severe	<i>Shigella dysenteriae</i> and <i>Shigella paradysenteriae</i> , varieties Shiga, Flexner, Sonne, Newcastle (Boyds 88) and Schmitz
	Amebic dysentery	Acute to chronic	Severe	<i>Entamoeba histolytica</i>
	"Food infection"	Very acute	Severe	<i>Salmonella</i> , chiefly <i>S. typhi</i> murium and <i>S. enteritidis</i>
	Cholera	Very acute	Very severe	<i>Cholera vibrio</i>
	Other bacterial infections	Variable	Mild	Slow lactose fermenting paracolon bacilli and pseudomonads are under suspicion
Parenteral and secondary diarrhea	Parasitic diseases	Variable	Variable	Various helminths and flagellates
	Parenteral diarrhea	Acute	Moderate to severe	Chiefly streptococci, also staphylococci and pneumococci, possibly viruses
	Tuberculous enteritis	Chronic	Severe	Tubercle bacilli
	Generalized infections	Variable	Variable	Variable
Noninfectious diarrhea	"Food poisoning"	Acute	Moderate to severe	Toxin producing staphylococci and possibly other organisms
	"Sewage poisoning"	Acute	Mild to moderate	Products of bacterial decomposition
	Nutritional diarrhea	Subacute	Mild	Dietary deficiency and "insults" to gastrointestinal tract
	Allergic diseases	Acute to chronic	Variable	Variable
	Neuro-psychiatric disorders	Chronic	Variable	Variable
	Other	Chronic	Severe	Local ulcerative or obstructive lesions such as those due to neoplasm and lymphogranuloma venereum
Diarrhea of unknown cause	"Epidemic diarrhea of newborn" *	Acute	Severe	Unknown

* Illustrative of various entities of unknown cause.

* In these cases the stools were first culturally examined during the acute phase of illness.
† In most of these cases fecal cultures were first made during the acute phase of illness.

The endemic disorders seen by us rarely had the character and the course of diarrheal disorders due to ingestion of toxic or irritating substances. Occasional household outbreaks could be classified as "food poisoning."

Our study of endemic diarrheal disease in Puerto Rico was limited. Such disease was frequently found due to *Shigella paradysenteriae*. It appeared that the morbidity and the mortality from this primary enteric infection were well above the rates in the other areas studied. However, there were various other etiologic factors involved, and the relative importance of each was not evident from our data.

We investigated 25 localized outbreaks of diarrheal disease. Sixteen (3 in military camps, 3 in civilian

The literature of the diarrheal diseases is notable for the variability in findings and conclusions. That *Shigella* infection of some type is the most important single cause has been supported by strong evidence. Flexner and Holt in 1903 were the first to present data leading to this conclusion.³ They reported on a study of acute diarrheal disease in 421 persons; 273 (66 per cent) had fecal cultures positive for the Shiga or the Flexner variety or both. These results obtained with early bacteriologic procedures at a cost of painstaking and tedious labor were not easily confirmed. In the subsequent study by others of more limited groups of patients, different factors (e. g. parenteral infection)

3. Flexner, Simon, and Holt, L. Emmett: Bacteriological and Clinical Studies of the Diarrheal Diseases of Infancy with Reference to B. Dysenteriae, Rockefeller Institute for Medical Research, 1903.

received attention and emphasis. The observations appear to have served as the basis for generalized opinion. There was an inadequate appreciation of what is now evident. The cause of diarrheal disease varies with area, with season and with age of persons concerned. Statements as to cause must be qualified and limited, not generalized.

EPIDEMIOLOGY

We present here our findings for *Shigella paradyseriae* infections and refer only briefly to the epidemiology of other diarrheal diseases.

The rates of incidence are admittedly based on incomplete reports, but in 1937 the rate for culturally proved cases of bacillary dysentery in New Mexico was 2.0 cases per thousand of population, while in 1938, with improved reporting, it was 3.6. South Georgia and Manhattan were studied simultaneously in 1939-1940 and the respective rates for proved cases of bacillary dysentery were 1.7 and 0.04 respectively. It was clear that this infection varied in incidence and occurred more frequently than was usually thought.

symptoms was eleven days, and the average duration of the convalescent carrier state was thirty-four days. The latter terminated by the end of one month in about 50 per cent of the cases but continued for more than ten weeks in 10 per cent. The duration of the passive carrier state appeared to equal approximately the total duration of infection in cases (i. e. the duration of symptoms plus the convalescent carrier state). With rare exceptions all carrier states terminated in less than one year. Chronic carriers, if there are any, are exceedingly rare.

The frequency of occurrence and the distribution by age of the passive carrier state were revealed through culture of fecal specimens from representatives of the general population. A total of 8,643 survey examinations for *Shigella* was obtained. The persons tested were selected by random sampling. The total discovered prevalence of *Shigella* infection (i. e. clinical patients, convalescent carriers and passive carriers) was 11 per cent in New Mexico, 4 per cent in Puerto Rico, 3 per cent in Georgia and 0.1 per cent in New York City. A maximum rate of 20 per cent was found

* This was the status on the day of examination

† These include incubatory carriers and person with positive fecal cultures whose status was uncertain

§ The data on New York City residents (1,630 cultures with 2 positive) are excluded

There was a definite concentration of culturally proved cases in the younger age groups in New Mexico and Georgia. The annual rate for infants under 2 years reached 30 per thousand in both areas. This rate declined through ages 2 to 4 years. Thereafter the morbidity was low, at the approximate level of 1 case per thousand of population a year. Most of the cases in New York City, in contrast, were distributed rather evenly throughout the first decade, with fewer cases in adolescents and adults.

Among the general population in New Mexico and Georgia the cases occurred chiefly during the summer and early fall. There was a pronounced concentration of cases among the poor. In household groups there were almost as many secondary infections as primary ones. Few young children in infected families remained free of disease. Furthermore, fecal specimens were collected from 219 of the household members who remained well, and 40 (18 per cent) were found to be passive carriers.

Convalescent carriers were identified in considerable numbers. A group of 103 patients whose fecal cultures had been positive were examined by serial cultures following recovery, and 82 (80 per cent) were found to be carriers. The average duration of infection with

in one village. A history concerning diarrhea was taken each time a specimen was secured. Thus we obtained cultural examinations and a record of the number of patients, convalescent carriers and passive carriers at that time. The findings are summarized in table 3. The total of *Shigella* infections was rather uniformly distributed by age. The highest rates were at ages 1 to 10 years. These were approximately twice those for the first year of life as well as those for the age groups above 10 years. Cases of disease, particularly those of severe disease which normally come to the attention of physicians, were definitely concentrated at younger ages. The passive carrier state was unusual at ages under 1 but increased in frequency with age. More than one half of the children found infected at 3 years and most of the infected older children and adults were passive carriers.

Of the 380 persons whose fecal cultures were positive, only 2 were under the care of a physician. One, acutely ill when found on survey, was admitted to the hospital the following day and died two days later. In the absence of a special study 2 might have been tested culturally, and thus there would have been 2 demonstrated and 378 undetected infections with *Shigella*. Hence for every known infection (manifest

source) there were numerous unrecognized infections (hidden sources). In the light of these findings it is not surprising that diarrheal diseases commonly appear as sporadic cases. These seemingly unrelated infections may arise from a single source or may be joined by a series of undetected infections. This knowledge is essential for the interpretation of the epidemiology of bacillary dysentery.

The relative frequency of carriers as compared with persons suffering from current diarrheal disease has been observed repeatedly in culturing fecal specimens from groups of institutional inmates. One example follows: An employee in a building which housed almost 200 low grade adult mental defectives had acute diarrhea which proved to be due to an infection with the W variety of the Flexner strain of *S. paradysenteriae*. No illness had been reported among the inmates, but fecal specimens from all were cultured. On one examination 26 were found to be carriers. This same variety of the Flexner strain was prevalent in inmates of another building who were younger; there were several clinical cases but even here the inmates with current disease were far outnumbered by the convalescent and passive carriers discovered by cultural surveys.

Some information relative to the immunologic response to *Shigella* infection was obtained through a study of institutional inmates. A preceding clinical infection provided a degree of protection against subsequent clinical attacks with the same variety of *Shigella* but little protection either against subclinical infection with the same variety or against clinical or subclinical infection with other varieties of *Shigella*.

Various modes of spread may be effective in the dissemination of these infections; the major question concerns their relative importance. We observed repeatedly a persisting high rate of infection localized in single buildings of institutions which had many buildings served by a common water and a common milk supply and a central kitchen. Flies were either well controlled or were absent because of the season of the year. Neither the water, milk or food nor the flies could be seriously suspected. This negative evidence indicated that the mode of spread was by a direct or an indirect person to person distribution of the infecting organisms.

In Albuquerque, N. M., some sections of the city were free of the disease while in others the infection was prevalent. All used the same water supply. Milk could not be the vector since the poor, who suffered most from dysentery, generally purchased the less expensive sterile canned or dried product. The Indians of the Southwest have a high incidence of diarrheal disease; they also use the sterile canned milk. We saw no evidence which suggested that the etiologic agents responsible for the diarrheal disease were brought into the households in water, milk or any other food product. The disease and the flies were found in the same environment. Still, cultural evidence suggested that flies do not carry *Shigella* frequently. We obtained only one positive result in repeated attempts to culture *Shigella* from pooled specimens of flies. In contrast pathogens of this genus were isolated with comparative ease from the fingers or from under the finger nails of culturally positive cases and carriers. On the basis of all evidence we are of the opinion that *Shigellas* are usually trans-

ported through the movements of infected persons (who are more numerous than has been supposed), chiefly those with few or no symptoms. Within the household and within larger groups living together the organisms are passed rather directly from person to person.

With respect to *Endamoeba histolytica* infection the high prevalence of cyst carriers has been reported repeatedly. However, clinical infection, acute or chronic, is comparatively rare. Both patients and carriers tend to be more numerous in tropical as compared with temperate and colder zones. In our experience apart from the Chicago outbreak cases were observed more frequently in institutions than elsewhere. In contrast to bacillary dysentery infection with *E. histolytica* was not often observed in infants; most of the subjects were adults.

The ameba carrier state is relatively chronic, its duration being measured in months rather than days and weeks as with bacillary dysentery. The cysts are moderately resistant and may be transmitted from person to person in a viable state through various channels. The wide distribution of *E. histolytica* is understandable. The unexplained observation is the striking variation in the reaction between host and parasite. In unusual instances the organism assumes the role of a highly invasive and destructive parasite; most commonly it is a seemingly innocuous organism. This striking difference in host-parasite relationship is the outstanding problem in the epidemiology of this condition, and indeed in the epidemiology of many diseases.

The *Salmonella* infections concerned in diarrheal diseases ordinarily come from animal rather than human sources. The organisms reach man through inadequately cooked meats and eggs, also in food soiled with the droppings of mice and rats. In outbreaks the cases occur within the one to seven day incubation period, though most have their onset on the second and the third day. Secondary cases may occur, but the convalescent carrier state is usually short and in general the infection soon disappears from the involved group.

Parenteral diarrhea is distinctive in its seasonal distribution, which coincides with that of acute infections of the respiratory tract. Outbreaks of staphylococcal food poisoning and "sewage poisoning" are highly explosive and ordinarily begin and terminate within a twenty-four hour period.

CLINICAL FINDINGS

In our studies of the acute diarrheal disorders in general population groups there were included 1,247 cases of diarrheal disease for which clinical as well as epidemiologic and laboratory data were collected. In assembling this series we attempted to secure records of all cases of diarrhea occurring within delimited areas. It is believed that the clinical findings on these cases more nearly represent the true picture of these disorders than the more commonly described observations on hospitalized patients.

One outstanding observation in the study of 555 patients whose stools were culturally positive for one or another variety of *Shigella* was the wide variation in severity of disease. There was a full range of clinical types from "just a few loose stools" at one extreme to fulminating, rapidly fatal illnesses at the

other. (In addition surveys of the general population revealed large numbers of asymptomatic carriers of *Shigella*.) Probably of equal importance was the observed fact that the commonest clinical manifestation was a "simple diarrhea." Abdominal pain, anorexia, nausea, vomiting and weakness were reported with frequency in the order named. Fever when present was usually an early manifestation, at times preceding and overshadowing the diarrhea, especially if the invading *Shigella* was of the Sonne or the Schmitz variety. Additional symptoms less frequently observed were tenesmus, dehydration, loss of weight, convulsions in children and chills in adults. Bloody "dysenteric" stools were seen rather infrequently even in cases of severe disease with positive fecal cultures.

The great majority of diarrheal disorders due to *Shigella* terminated spontaneously with clinical recovery within a week; those in adults usually in from two to four days. The illnesses in infants were more prolonged, and all 39 fatalities observed were in children under 2 years of age.

Amebic dysentery cannot be differentiated from bacillary infection on clinical grounds alone. In general, clinical amebiasis has a more gradual onset, slower evolution and a greater tendency toward chronicity of symptoms. With acute symptoms the stools are commonly "bloody."

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of endemic acute diarrheal diseases can be made with certainty only in the laboratory by isolation of the specific etiologic agents. Since this involves delay and since the specific chemotherapeutic agents now available for some of these disorders should be given promptly, satisfactory working diagnoses are needed. We suggest below two aids for the establishment of these.

As a first requirement, the most probable diagnosis in the particular area and group must be known. Prior to our studies in New Mexico and Georgia, *Shigella* infection was thought to be rare and bacillary dysentery was not diagnosed. It was discovered in our work that many of the usual cases of endemic diarrhea, particularly the ones of severe diarrhea, were due to *Shigella*. From these data the local physicians may know that most of the patients with acute diarrhea who come to their attention have specific enteric infection due to some variety of *Shigella*. This type of information can be collected through the cooperation of physicians and health departments and should be readily obtainable in military units. Without it the endemic diarrheal disorders will continue to be poorly diagnosed. There must be also an adjustment of the prevailing concept of the clinical nature of "shigellosis"—it must be appreciated that the varieties of *Shigella* which prevail in this country rarely give rise to the severe bacillary dysentery usually described in medical texts.

Our findings in all areas studied show that *Shigella* paradysenteriae infection is to be considered as the most probable diagnosis for endemic acute diarrhea occurring in older children and adults, particularly during the warm seasons. This is also true of intestinal disorders of younger children and infants in the South and the Southwest. Other causes, such as parenteral infections and dietary factors, appear to be more commonly involved in early infancy.

A consideration of amebic dysentery is the first step leading to an accurate diagnosis, and this disease is

to be considered when persisting, acute, usually "bloody" diarrhea occurs sporadically.

Acute diarrhea caused by *Salmonella* cannot be differentiated clinically from that due to *Shigella*. The former tends to give a higher elevation of temperature, more vomiting, greater abdominal tenderness and less blood in the stools. A certain diagnosis must await laboratory findings.

"Food poisoning" due to *Staphylococcus* is characterized by a brief and stormy course with distressing vomiting, severe diarrhea and little if any fever.

The diagnosis of epidemic diarrheal disease is commonly a joint responsibility of the practitioner and the public health officer. Here the nature of the outbreak provides added information of diagnostic significance. The highly explosive epidemic in which both the outbreak and the cases continue for only a few hours is typical of staphylococcal "food poisoning" and of so-called "sewage poisoning." Infections with true enteric pathogens also occur in explosive outbreaks, but here onsets are distributed through a period of three to seven days, with a peak on the second or the third day. These are most commonly due to some variety of *Salmonella*, rarely to *Shigella*. Epidemics due to the latter ordinarily continue throughout a period of several weeks. Characteristically groups previously free from infection at first begin to have sporadic or endemic cases which gradually increase in number. The peak in incidence may be reached only after a month or more. The decline in clinical cases may be more rapid, but the *Shigella* infection persists thereafter for prolonged periods in convalescent and passive carriers.

LABORATORY DIAGNOSIS

Recent developments in bacteriology have increased the reliability of diagnostic cultural tests for enteric infections. Highly selective mediums which permit growth of the enteric pathogens but inhibit growth of most of the nonpathogens are now available. Fecal specimens obtained by rectal swabs may be used for immediate direct inoculation of the selective mediums. (An ordinary cotton tipped applicator in a small rubber tube having its distal end lubricated is effective and convenient.) For *Shigella* infections plates of S S agar or desoxycholate citrate agar are used. The surface of the medium is "painted" with the swab. For *Salmonella* a broth enrichment (selenite F or tetrathionate) is also indicated. Suspected colonies are picked and identified through standard and relatively simple cultural and serologic tests. By using this highly effective procedure, fecal specimens from patients and their contacts may now be cultured in substantial numbers. This examination may and should be employed freely as the most reliable laboratory diagnostic test; it also can be effectively used for the identification of carriers, which is of obvious importance for control purposes.

Microscopic examination of a fresh warm fecal specimen is indicated when amebic dysentery is suspected. Motile amebas with typical characteristics are frequently present in large numbers. Under these conditions a laboratory diagnosis of amebic dysentery may be made with little probability of error. Reliable identification of cysts is more difficult and requires a highly trained worker.

Agglutination tests with the patient's serum cannot be interpreted with sufficient accuracy to warrant the use of this procedure in diagnosing diarrheal diseases.

TREATMENT

Chemotherapy has a place of major importance in the treatment of diarrheal diseases. Emetine and the iodine and arsenic compounds have long been available for amebic dysentery. More recently the sulfonamides have established their place in the therapy of bacillary dysentery and are effective in the treatment of many of the parenteral infections responsible for diarrhea. Specific therapy is not available for *Salmonella* infections or the "epidemic diarrhea of the newborn." General supportive measures only are needed in "food poisoning" and similar types of diarrhea of short duration.

Two types of sulfonamides are available for bacillary dysentery. There are the poorly absorbed compounds which may be maintained at a high concentration in the intestinal contents while the level in the blood remains low, and there are the more readily absorbed sulfonamides which are also of value in enteric infections. We have studied the clinical and bacteriologic response to three poorly absorbed and five well absorbed compounds. The response to sulfaguanidine, succinylsulfathiazole, sulfadiazine and sulfathiazole has been reported. Since that time we have used these and sulfamethazine, sulfamerazine, sulfapyrazine and sulfathalidine (phthalylsulfathiazole) in more than 1,000 additional persons proved to be infected.

It was evident through a comparison of findings in untreated controls that these sulfonamides all were beneficial in patients with "shigellosis." Flexner varieties of *S. paradyenteriae* were most sensitive to these preparations and Sonne the least. In general the response to the poorly absorbed sulfonamides tended to be delayed, commonly becoming clearly evident clinically and bacteriologically only after twenty-four hours or more of treatment. There was an earlier response to sulfadiazine and apparently also to the newer well absorbed sulfonamides now under observation. Sulfathiazole has been satisfactory in persons with the Flexner variety of infection but has not evoked as favorable a response as other well absorbed compounds in those infected by the Sonne variety.

Pathogenic types of *Shigella* presumably do not grow diffusely throughout the contents of the enteric tract, but rather on or in the wall of the bowel. The absorbed sulfonamides are present in the blood stream, and irrespective of route of administration are soon found in high concentrations in the enteric tract. They are rapidly brought by the blood stream to the site of pathologic activity and approach the organisms both from the tissues and from the lumen. The observed response of *Shigella* infections to absorbed sulfonamides is therefore understandable.

The dose of sulfaguanidine or of succinylsulfathiazole is large, 5 Gm. three times a day for adults being a minimum. During the acute phase of illness, four to six doses may be given daily. We used the well absorbed sulfonamides in 1 Gm. doses three and four times a day in adults. For all preparations the initial dose was twice the maintenance dose. The infections in patients under treatment were followed by daily culture of stools. Medication was discontinued after two consecutive cultures were found negative. On the basis of observations a minimum period of treatment of five days is recommended, to be extended to seven to ten days for infections by the Sonne variety. In all

clinical cases treatment should continue for two days following the cessation of symptoms.

Reports in the literature indicate that *Shigella dysenteriae* (Shiga's bacillus) is inhibited in patients treated with sulfonamide compounds. The data do not indicate the relative sensitivity of this organism to these compounds nor the comparative efficacy of different preparations.

The acute symptoms of amebic dysentery are controlled by emetine hydrochloride, but this drug is a relatively ineffective amebicide. It is a toxic preparation and must be used with caution. The dose for adults is 1 grain (0.065 Gm.) per day, and its use should not be continued longer than the duration of the acute manifestations, with six days as the recommended maximum. For patients with amebic abscess emetine is the only drug of proved value. The available iodine and arsenic preparations are more effective for carriers of the cysts of *E. histolytica*. The dosages for adults are chiniofon 1 Gm. three times a day for seven days, vioform 0.25 Gm. three times a day for seven days, diodoquin 0.5 to 0.75 Gm. three times a day for eighteen to twenty days and carbarsone 0.25 to 0.5 Gm. twice daily for ten days. All these courses of treatment with iodine and arsenic preparations may be repeated if necessary two weeks after completion. If one proves unsuccessful, another may be tried.

CONTROL

Before sulfonamides became available, control measures were directed to the prevention of direct and indirect spread of human excreta from person to person by means of animate or inanimate vectors. Wherever possible this is still the method of choice since improved sanitation and personal hygiene invariably result in better general health for the individual and the community.

Food poisoning may be prevented by proper care in the handling and preparation of foods. Inadequate cleansing of the hands of the cooks, incomplete cooking of foods and long periods of storage after cooking of custards, puddings and salads are the usual causes of these outbreaks. Insistence on proper care in the kitchen will prevent their occurrence. This is essential also for the prevention of outbreaks due to *Salmonella*. If cooking is sufficient to raise the temperature throughout all the food being cooked to the thermal death point of these organisms, epidemics of this type will not occur. That they do occur is largely the result of the inadequate recognition of the time required to raise the temperature in the center of a whole fowl, for example, to such a level.

Radical measures are recommended for the control of epidemic diarrhea of the newborn. Nurseries affected are rigidly quarantined. No new admissions are permitted. The sick are separated from the well, and when possible the latter are discharged to their homes. The nursery is permitted to reopen only after thorough sterilization and a vacancy of two weeks.

The problem presented by *Shigella* infections is more complex. In the general population sanitary measures are a definite aid, but these have not as yet eliminated infections by specific enteric pathogens. In many areas the economic level of the population is such as to preclude effective steps in this direction at present. Adequate treatment of patients with recognized disease will remove some sources of infection, but since patients

with unrecognized infections and persons with sub-clinical infections are more common, this alone cannot be expected to reduce materially the incidence of endemic disorders. This statement is supported by two attempts to control the spread of *Shigella* infections (one in a military group and the other in an institution) by administering sulfonamides to all patients irrespective of the severity of their infection as soon as enteric disorders developed. In neither situation were we successful in eradicating or materially reducing the incidence of disease.

In military groups and institutions careful attention to personal hygiene will do much to decrease the incidence of infectious diarrheal disease. When troops have been stationed in permanent well sanitized camps the diarrheal disorders have been a minor problem. Surveys for carriers under these conditions have shown a low prevalence of *Shigella* infections. The same is true of institutional inmates who are cleanly in their habits and who are housed in a sanitary environment.

However, *Shigella* infections do gain entrance to groups living under less favorable hygienic conditions. Here they tend to spread widely and remain persistently. In military practice this is most likely to occur among troops in new or temporary camps, during field maneuvers or under battle conditions. Among institutional inmates the mentally disturbed patients and the low grade defectives are particularly involved. A high incidence of carriers is found in association with patients showing bacillary dysentery. Two control procedures have been tested for such heavily infected groups: (a) Wherever relatively simple laboratory procedures are available, it is practicable and effective to identify carriers by cultural surveys and to treat all patients and carriers till their stools are culturally negative. The reduction of a high to a very low incidence is readily attained, but complete eradication of all *Shigella* infections is more difficult. (b) The use of small doses of sulfonamides for all persons in such groups also appears promising. A prompt decline in both patients and carriers followed the beginning of this form of preventive therapy in seven groups observed to date. The method must be studied further before it can be recommended as a general control procedure.

In the control of amebic dysentery we urge the necessity of prompt diagnosis and adequate specific therapy to prevent the continuation of the illness and to remove the hazard of death. With regard to the question of treatment of asymptomatic carriers of *E. histolytica* we believe that widespread effort to detect and treat such persons is impracticable and uneconomical. However, the carrier detected by a physician on routine examination should be treated with one of the iodine or arsenic preparations previously mentioned.

NOMENCLATURE

The term dysentery as ordinarily used implies "bloody stools." The designation bacillary dysentery so interpreted would apply only to unusual cases of *Shigella* infection. A name referable to the etiologic agent would be preferable. In line with the accepted use of "brucellosis" for all *Brucella* infections, we recommend the adoption of "shigellosis" for all infections due to pathogenic varieties of *Shigella*.

National Institute of Health.

PRESENT DAY, PROBLEMS OF MALARIA INFECTIONS

MARK F. BOYD, M.D.

TALLAHASSEE, FLA

DIAGNOSIS

Malaria infections, either acute or chronic, may be suspected in persons who (a) give a history of having had an attack within the previous two or three years. (b) who have been residents or transients in an area where these diseases are endemic, (c) who exhibit an anemia or splenomegaly otherwise unexplainable, (d) who present an acute febrile illness characterized either by a remittent fever or by intermittent febrile paroxysms with or without rigors and unaccompanied by a leukocytosis and (e) who present any illness with a comatose onset. Furthermore, unsuspected chronic latent infections may become clinically activated by (a) a change in residence involving a material change in climate, (b) traumatic injury including surgical treatment and (c) confinement. The possibility of a malaria infection must not be overlooked in the recipient of a transfusion who develops fever.

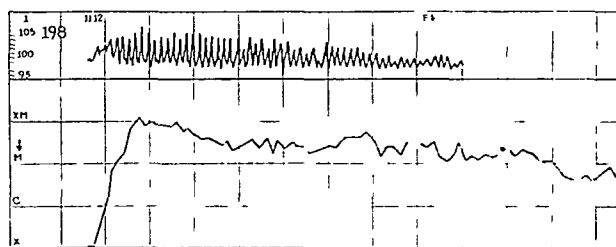

Chart 1—Naturally induced vivax infection terminating spontaneously. Prepatent period eleven days, incubation twelve days, first clinical reaction with density of 10 parasites per cubic millimeter. Remittent fever from 12th to 14th day, insensibly changing to intermittent quotidian. Spontaneous suppression of paroxysm on the 40th day unexplained. Note gradual decline in temperature from maximum of 107 F. in paroxysm on 19th day to 60th day, when it does not exceed 100 F. Maximum parasite density of about 12,000 per cubic millimeter also on 19th day. Clinical activity ceases spontaneously with concurrent parasite density of about 1,800 per cubic millimeter and is still in excess of 400 per cubic millimeter on 93d day from inoculation.

The charts represent the day by day progress of (a) the clinical activity of the infection as reflected in the temperature and (b) the parasite density. The first is displayed in the upper portion of the chart and represents the temperature curve in degrees Fahrenheit taken at four hour intervals. The lower portion, on a semilogarithmic scale, represents by a solid line the density of total parasites (trophozoites and gametocytes) per cubic millimeter as determined from smears routinely taken at about 8 a.m. If the gametocyte density is shown, it is represented by a line of dots and dashes. The lowest line of the 1st cycle of ruling represents a density of 10 parasites per cubic millimeter, the second 100, the third 1,000, the fourth 10,000 and the fifth 100,000. The vertical lines mark the days elapsing since the inoculation by means of infected mosquitoes, the day of which is further marked by the arrow.

By the terms of our definition a definitive diagnosis must be based on the detection of the parasites in a blood smear. Other tests, largely of a serologic nature, have been proposed, some of which may have merit. From the standpoint of convenience and speed these are not, in my opinion, likely to supplant the examination of blood smears. In consideration of laboratory reports, it should be borne in mind that a single or even several negative examinations are insufficient to exclude

This paper, in a symposium on "Tropical Diseases," is published under the auspices of the Section on Practice of Medicine

Owing to lack of space, this paper has been abbreviated for publication in THE JOURNAL. The complete paper appears in the author's reprints.

The studies and observations on which this paper is based were conducted with the support and under the auspices of the International Health Division of the Rockefeller Foundation, in cooperation with the Florida State Board of Health and the Florida State Hospital.

the existence of a malaria infection. On the other hand, the detection of a single parasite of unimpeachable morphology is sufficient to recognize the existence of such an infection but would not necessarily justify the attribution of the patient's symptoms to their presence.

Blood smears for malaria diagnosis should be taken with the utmost care and should afford a thin and thick smear on the same slide. The limitations of space do not permit a discussion of the technics for making and staining smears and the morphologic identification of parasites. These are given by Wilcox.⁵ The recent ingestion of antimalarial drugs by a person with a latent infection may make parasites undetectable for some days thereafter. The examination of a thick smear for five minutes is roughly equivalent to the examination of a thin smear for fifteen minutes, thus effecting material saving of time in a busy laboratory. If parasites are not detected within this time it is hardly worth while to spend further time in the examination of this smear, as it is preferable to collect further smears on the following days. However, delays in diagnosis incidental to low parasite densities will not adversely affect later therapy. The report should if possible also specify the identification of the species of any parasite observed. In the event of a diagnosis of falciparum, it is particularly desirable to deter-

Chart 2.—Naturally induced vivax infection, with an induced remission followed by a series of recrudescences and a relapse. The incubation period was of ten days, the prepatent period eleven days. Attack an intermittent quotidian from onset. However, on 15th and 16th and again on 17th and 18th the febrile periods were of about thirty-six hours' duration, with bifid peaks. While common in falciparum infections, these protracted paroxysms are unusual in vivax malaria. A single 10 grain (0.65 Gm.) dose of quinine sulfate given on the 33d did not affect the paroxysm on that or the following days. It did result in a definite depression of the parasitemia, which reached a minimum on the 38th day. Coincident with this depression, a remission occurred which lasted from the 35th to the 40th day. Although the density of the parasitemia was again as high on the 42d day as it was when the quinine was given, it did not remain sustained but underwent a succession of four further depressions and rises, with a clinical remission occurring at each depression and a renewal of clinical activity during each rise. The first four rises are recrudescences, the fifth is a relapse. Note that each period of renewed clinical activity is initiated by tertian paroxysms.

mine the density of parasites per cubic millimeter, for it must be remembered that the clinical attack is but a reflection of the course of the parasitemia. For this the method of Earle and Perez⁶ is useful. It is also desirable to control the effectiveness of the treatment of acute malaria by the daily examination of blood smears continued until the smears become negative.

The lowest parasite density which may be recognized by examination of a smear for the time suggested is approximately 10 parasites per cubic millimeter. In highly susceptible persons clinical activity may, as already noted, be initiated by lower and submicroscopic densities. On the other hand, at the onset of relapses the parasite density will be high, often several thousand per cubic millimeter, as might be expected in a partially immune person (charts 2 and 3). Quartan and vivax

infections commonly exhibit a ceiling to the maximum parasite densities attained. The quartan parasitemias seldom exceed 10,000 per cubic millimeter (chart 8) and those of vivax seldom exceed 50,000 per cubic millimeter (charts 1, 2, 3 and 4). On the other hand, the falciparum parasitemia has no potential limits (charts 5, 6 and 7) and it is important to note that the prognosis is definitely bad if the count attains or exceeds 500,000 per cubic millimeter. The employment of provocatives in suspected latent infections, either to expel parasites from the spleen or to induce a relapse, have not, in the hands of my associates and myself, given sufficiently consistent results to warrant their routine utilization as aids to diagnosis.

It is a matter of regret that many physicians practicing in endemic areas, have based diagnoses of malaria infections on clinical histories, as some still do, and often on the relation by a patient of obscure and, for malaria, atypical complaints. While recognizing that an experienced practitioner will often, perhaps usually, correctly recognize typical intermittent attacks from their clinical manifestations alone, I am of the opinion that this is nevertheless an unfortunate and undesirable practice. It has undoubtedly resulted in ascribing to malaria many conditions for which these infections are not to blame⁷ and has probably contributed in no little degree to the extent to which real or imaginary sufferers indulge in self medication. The burden of proof lies on the diagnostician.

SALIENT CLINICAL FEATURES

Although malaria is a self limited disease, comparatively few physicians in the centuries which have passed since the introduction of cinchona have had opportunity to observe the uninterrupted evolution of these infections, as in general they felt in duty bound promptly to administer the bark, or later the alkaloids, and hence abruptly to interrupt the attack. Therefore the application of induced malaria to the therapy of neurosyphilis, particularly when naturally induced, affords a unique opportunity to reappraise and verify ancient knowledge and extend observations of the experimental disease along modern lines of investigation.

Clinically active malaria infections regardless of the species of their causative parasite exhibit three basic symptoms: (a) fever, (b) anemia and (c) splenomegaly. The first two are definitely related to the development of the parasites, as the fever occurs at the time of their multiplication, and the anemia arises from the destruction of the erythrocytes on which the parasites have fed. The specific infections, particularly falciparum malaria, may in addition exhibit other and very striking symptoms. To one who wishes to pursue this subject further the classic monographs of Marchiafava and Bignami⁸ and Mannaberg⁹ still offer the best extended clinical descriptions.

Fever is the most striking manifestation of clinical activity and may at times be remittent but is more commonly intermittent. Vivax infections in susceptible persons frequently present a remittent fever for a period of from three to five days at the onset (chart 1). Falciparum infections likewise often exhibit a remittance (chart 7). Although such sustained temperatures

are clearly due to lack of synchronization in the sporulation time of the parasites, pronounced secondary rises or peaks are usually noted, which indicate the sporulation of large groups of parasites and forecast the later intermittence. The transition from remittance to intermittence is thus usually gradual. The intermittent paroxysms may recur every day (quotidian, chart 1), every other day (tertian, charts 2, 3, 4, 6 and 7) or every fourth day (quartan, chart 8). In the intervals between paroxysms the temperature oscillates within normal limits. About ten days after the onset of the primary attack in susceptible persons, or at the onset of a relapse, the paroxysm is often initiated by a rigor or chill, which may vary in intensity from a slight subjective sensation of chilliness to involuntary muscular contraction accompanied by a sensation of extreme cold. The temperature is meanwhile rapidly rising, but before the peak of the fever is reached the patient is no longer cognizant of cold. At the maximum of elevation, which is not long sustained, profuse perspiration sets in, and the temperature rapidly falls as in a crisis. With the return of normal temperature the patient may become ambulatory and except for a sensation of weakness the vivax infected patient may offer no complaint. However, the quartan paroxysms are definitely more exhausting and the protracted falciparum paroxysms still more so. The period during which the temperature remains elevated during a paroxysm varies with the different infections, in vivax for from six to twelve hours, in quartan from eight to twelve hours and in falciparum malaria from six to thirty-six hours. The vivax and quartan paroxysms usually exhibit a rapid and symmetrical rise and fall of temperature to and from the peak. The protracted falciparum paroxysms may have a sustained period of elevation or have bifid or trifid secondary temperature peaks (chart 7). The regularity and uniformity in the successive paroxysms in vivax and quartan malaria is in sharp contrast to the irregular and asymmetrical fever curve of the paroxysms of falciparum malaria. The maximum temperature attained in a vivax or quartan paroxysm varies to some extent with the current density of the parasitemia and may briefly attain as high as 107 F. or more with no immediate risk to the patient or forecast of a dangerous trend in the infection. On the other hand, an observation of 104 F. or higher in falciparum malaria, particularly if the course is remittent, suggests that the infection may soon get out of hand. It should be stressed that primary vivax infections usually exhibit a series of quotidian paroxysms and that tertian paroxysms are not usually seen until the attack is wearing out or during relapses (charts 2 and 3). Quartan infections usually present paroxysms recurring every fourth day (chart 8) but, as the infection evolves, a new cycle may be injected and the patient will exhibit paroxysms on two consecutive days followed by one paroxysm free day and finally, with the appearance of a third cycle, develop quotidian paroxysms. Thus quotidian paroxysms in vivax malaria are due to the division of two alternating broods of parasites, each requiring forty-eight hours for maturation, and in quartan malaria to the division of three consecutively maturing and overlapping broods, each requiring seventy-two hours. As the infection progresses, synchronization of the parasites improves and the duration of the paroxysm diminishes, while a diminution in the maximum elevation of the temperature forecasts early

extinction of clinical activity by the corresponding brood of parasites (chart 1). The alternating parasite broods which produce vivax quotidiens are not indicative of inoculation on two successive days (charts 1, 2 and 3). While the paroxysms due to any brood in vivax and quartan infections tend to recur at the same hours, more frequently afternoon than forenoon, some broods for reasons not understood take less or more than the conventional forty-eight or seventy-two hours and hence the paroxysm cycles recur earlier (anticipation) or later (postponement) and may finally run around the clock.

Some patients with grave falciparum infections will not subjectively complain of fever but exhibit a cold skin and clammy perspiration, with cyanosis of the extremities. This often accompanies manifestations of gastrointestinal symptoms. It may occur at the onset or after several more or less typical paroxysms.

The development of the anemia may be gradual or rapid and is accompanied by a pallor to which vasomotor disturbance might contribute. It develops most slowly and to the least degree in quartan infections, probably because of the slower growth and lesser density of these parasites, as well as from their predilection for the aging erythrocytes. It progresses more rapidly

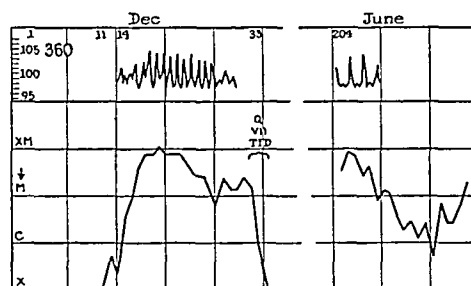

Chart 3—Naturally induced vivax infection, with spontaneous remission during which divided doses of quinine were given during three days, patient later experiencing a recurrence. Note prepatent period of eleven days, incubation period of fourteen days. Slight remittance for three days after onset, followed by protracted paroxysms on 17th 18th and 19th 20th, with bifid peaks, thereafter proceeding as a quotidian. Termination of attack spontaneous on 30th with about 1,500 parasites per cubic millimeter. During the remission 7 grains (0.45 Gm.) of quinine was given twice daily for three days, which drove the parasitemia to submicroscopic levels. On the 204th day following the inoculation the patient had the first renewal of clinical activity, which initiated the first of a series of four tertian paroxysms. The day following the first paroxysm of the recurrence, a parasitemia of about 3,500 per cubic millimeter was observed.

in vivax infections and is probably intensified by the predilection of these parasites for the reticulocytes. Most rapid progress, however, is seen in falciparum infections, which is attributable not only to the greater parasite density attained but by their attack on erythrocytes of all ages. The anemia is hypochromic in type. Since the iron stores are not depleted by this destruction of cells, progress toward restoration of blood loss is rapid during remissions. It is interesting to note that spontaneous remissions usually occur in vivax infections when the erythrocytes are reduced to about 1.5 million per cubic millimeter with hemoglobin about 4.0 Gm.

Enlargement of the spleen is detectable during the second week following the primary onset. The splenic border is rounded, the organ is obviously tense and palpation may be painful. In one attack the enlargement may bring the lower pole to the vicinity of the umbilicus in the course of two or three weeks. With cessation of clinical activity the congestion may rapidly subside or some degree of enlargement may persist indefinitely. Such persisting enlargement suggests

that a latent infection continues.¹⁰ The contracting spleen appears flaccid to the palpating fingers and is found lying more toward the left flank. With repeated enlargement due to either relapses or reinfections the organ may extend to the pelvis, fibrosis develops, probably stimulated by the pigment deposits, the substance becomes firm, the border is sharp, and involution proceeds slowly. The liver may also be enlarged and tender.

Albumin is frequently noted in the urine in amounts exceeding a trace, in infections produced by any species of parasites. However, this is most variable in vivax infections and most consistently noted in quartan infections. In falciparum and quartan this is usually associated with a depression of the plasma albumin. During the period of this depression there may be rises in the globulin and englobulin values. Edema of the extremities is least commonly observed in vivax infections and is most frequent with quartan. In the latter its occurrence may be anticipated with depression of the plasma albumin. The conjunction of edema, albuminuria and reduction in plasma protein leads to the conclusion that a malaria infection produces a nephrosis rather than a nephritis.¹¹

In vivax, but more particularly in falciparum infections, the maturing parasites exhibit a tendency to recede from the peripheral to

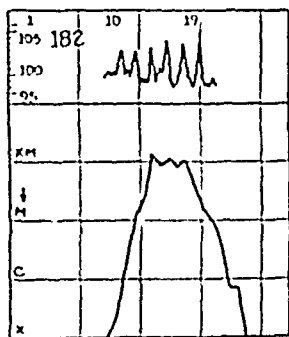

Chart 4.—Naturally induced vivax malaria with early spontaneous termination. Prepatent period ends on 10th day and incubation ends on 11th day, initiating a series of tertian paroxysms which cease spontaneously on the 21st day. Note the rapid spontaneous decline in the parasitemia beginning on the 20th day and descending to submicroscopic levels on the 27th day. This patient must have had previous experience with some other strain of vivax parasites, as he exhibits a heterologous immunity.

the visceral circulation as sporulation time approaches. This is so noticeable in the latter infection that segmenting forms are but rarely seen in smears of peripheral blood unless the infection is overwhelming. This is important in the interpretation of parasite counts made on paroxysm days but prior to the paroxysms, as these will be much lower than those observed in the interpyrexial days (charts 5, 6 and 7). In this retreat the parasites, for reasons unknown, appear more particularly to congregate in the capillaries of some particular viscus of the cerebrum, lungs or intestine. Since the erythrocytes infected with these parasites appear shrunken and rigid and, owing to a coating of fibrin appear adhesive,¹² they produce extensive capillary blockade. Consequently falciparum infections more particularly may present additional striking and variable symptoms, which are often referable to the viscus in which sporulation is occurring and which may mislead the physician unless blood smears are routinely taken. Space does not permit detailed discussion of these nearly infinite variations, which have received elaborate clinical classifications,¹³ but special mention may be made of (a) continued fever with or without hyperpyrexia, (b) hypopyrexia, (c) various

cerebral manifestations including coma, delirium and convulsions, (d) various symptoms referable to the gastrointestinal tract including persistent vomiting, often bilious, dysenteric or diarrheal evacuations, sometimes with hemorrhage from the bowel, (e) symptoms suggesting acute bronchitis or pneumonia, (f) weak pulse and syncope, thrombosis and hemorrhages, edema and dropsy, acute progressive anemia, sometimes hemolytic, (g) icterus, (h) albuminuria, hematuria and hemoglobinuria. The latter condition is often differentiated as blackwater fever.

Untreated primary attacks may vary greatly in their duration, depending on the degree of the patient's susceptibility and the species of parasite. Quartan infections may continue clinically active for as long as nine months (chart 8), vivax infections, spaced out by spontaneous remissions, may continue for approximately one hundred days (chart 2), although if remissions do not intervene I have not observed them to exceed nine weeks (chart 1), while falciparum infections are the shortest and will not often exceed six weeks in duration (charts 6 and 7). In these protracted infections the severity of the paroxysms gradually diminishes coincident with a reduction in the elevation of the temperature. The change may be more pronounced in one cycle than the other, in which case the cycle most affected may drop out and the course is continued as a tertian. The termination of the course is similar to a lysis (chart 1). In my opinion any clinical activity noted within these limits, even though interrupted by one or more spontaneous remissions, is essentially attributable to the primary parasitemia. In such patients clinical activity ceases while the parasite density is still high (chart 1), and the latter gradually decreases but persists at microscopic levels for several weeks.

In falciparum infections gametocytes are not observed until about ten days after the first appearance of trophozoites (charts 5, 6 and 7). Their appearance is frequently made manifest by a sharp decline in the density of trophozoites often sufficient to produce a clinical remission. This may mark the end of the attack (chart 5). In more susceptible persons trophozoites will return to pyrogenic levels in about ten days more, and clinical activity will be resumed (chart 6). A falciparum attack will consist of one or more such units of alternating waves of trophozoites and gametocytes (charts 6 and 7). In vivax infections gametocytes are present practically from the onset, while in quartan their production is scanty and irregular. Since both clinical activity and gametocyte production are proportional to the density of the parasitemia, those who are, or who have recently been, clinically ill will be the most infectious to anophelines, both qualitatively and quantitatively. After latency is well established, patients may again become slightly infectious if subclinical rises occur in their parasitemia.

However, vivax and quartan infections whose natural evolution has been interrupted by early remissions therapeutically induced show a definite and annoying tendency to resume clinical activity at a later date, even after the lapse of a year or more (chart 3). Falciparum infections probably do not persist in a latent condition for more than a year, vivax may persist for two or perhaps even three years, while quartan latency may persist for protracted and unpredictable periods. Resumption of clinical activity, if occurring within eight weeks of the cessation of the primary attack, is dis-

tinguished as a recrudescence (chart 2) and, since practically all these arise within one hundred days of the onset, before the primary parasitemia has descended to submicroscopic levels, should properly be regarded as part of the primary attack. Further clinical activity occurring in from eight to twenty-four weeks after the cessation of the primary attack is designated a relapse, and if arising after an interval longer than twenty-four weeks it is known as a recurrence (chart 3).

Persons who have had previous experience with other strains of the same species of parasite will experience attacks of varying duration but usually of not over two weeks (chart 4). These terminate abruptly with a rapid decline in the parasitemia.

TREATMENT

The treatment of malaria infections is symptomatic and specific. The former is practiced concurrently with the specific, chiefly to alleviate symptoms which distress the patient or interfere with specific treatment; specific therapy is directed to the destruction of the parasites.

Until the fever is checked the patient should be confined to bed, while for two weeks subsequently activity should be limited to very moderate ambulatory exercise.

If the hyperpyrexia observed during a paroxysm is due to sporulation of parasites alone, its duration will be transitory and will rarely require interference except for the comfort of the patient. If it persists it may be suspected that the cerebral heat centers are affected. In this case tepid sponging or cold baths may be employed, their duration being controlled by the rectal temperature. During this time an abundant intake of cool fluids should be encouraged, which should be supplemented by sodium chloride. When free perspiration is begun the patient should be rubbed dry and changed to dry clothing. On the other hand, if the temperature is subnormal the patient should be well provided with covers and numerous hot water bottles. Several sinapisms should be applied to different parts of the body, and hot beverages should be supplied. Since these patients often suffer from constipation, purgation should be effected if necessary, and daily doses of liquid petrolatum given subsequently. Nausea, and vomiting in particular, may interfere with the oral administration of specific drugs. They may often be controlled by cracked ice with or without lime water. If uncontrollable by this means, 5 minims (0.3 cc.) of tincture of opium or 5 to 20 grains (0.3 to 1.3 Gm.) of chlorobutanol may be given. Other symptoms are appropriately met as the need arises. Patients with edema should receive a high protein diet, and those with icterus a high carbohydrate and vitamin diet.

An excellent discussion of the treatment of malaria, based on an extensive experience, has been presented by Dove,¹⁴ while the monograph of Field¹⁵ is the most exhaustive recent treatise. The Fourth General Report of the Malaria Commission of the League of Nations should also be consulted.¹⁶

The specific treatment of malaria is parasitocidal and must take into consideration the different stages of the

parasites which are concerned with the human host, namely the infecting or sporozoite stage, the vegetative (trophozoite) stage, to the multiplication of which clinical activity is due, and the gametocytes which render the patient infectious.

Of recent years the specific therapy of malaria has undergone profound modification, owing (1) to an enlargement of the physician's armamentarium by the introduction of the useful synthetics plasmochin and atabrine, (2) to the recent capture of the principal areas of cinchona production by the enemy, which have caused available stocks of the alkaloid quinine to be reserved for military use and the substitution therefor of totaquin, a standardized preparation containing all of the crystallizable alkaloids present in American barks, and (3) the possibility that current research may result in the discovery of still more efficient synthetics. Information of progress in this field of research will likely be withheld until the end of the war. Present dosage regimens of antimalarial drugs have largely developed empirically. It is hoped that present studies on attainable concentrations in the blood will permit of their more scientific utilization.

SUPPRESSIVE TREATMENT

Quinine has been routinely taken for years by those resident in endemic areas, and of later years atabrine has been similarly ingested, in the belief that it will

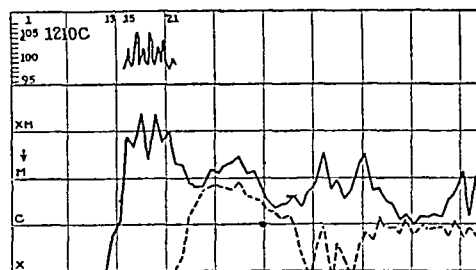

Chart 5.—Naturally induced falciparum malaria in a Negro patient, the attack terminating spontaneously. Prepatent period ends on 13th day, incubation period on the 15th day. Attack consists of a series of six unequal quotidian paroxysms. The cycle of the day of onset, on that and the subsequent days of its tertian reappearance, is distinctly weaker than its alternate. The maximum parasite density attained was about 24,000 per cubic millimeter, a low density for this parasite. Clinical activity ceased spontaneously because of a coincidental drop in the parasitemia density on the 22d, on which day gametocytes were first seen. The trophozoite minimum was reached on the 26th, they increased slightly for five days thereafter, and then they underwent a second decline and a further rise, neither of which was accompanied by clinical activity.

ward off infection from the bite of an infected mosquito. Any drug that might possess the property of destroying sporozoites or the succeeding stage of the parasites would be a true causal prophylactic. Unfortunately quinine does not possess this property, nor is it dependably exerted by atabrine, nor is there any other known available drug which possesses this characteristic. This deficiency in these drugs, or misconception of their properties, should not however deter us from their employment under certain circumstances. While they will not prevent a person from contracting infection, they will check the multiplication of parasites sufficiently so that most protected persons will not develop active clinical malaria during the period in which they are ingested. Their employment is thus more appropriately described as suppressive treatment. Their routine distribution where large bodies of men are suddenly brought in an emergency into unsanitated areas for construction or military purposes will temporarily avoid the incapacitation of many from malaria. However, on the withdrawal of these men from such areas and with the suspension of treatment many will develop

acute clinical malaria about two weeks later. As at present practiced, adult males are given 0.1 Gm. of atabrine daily at the evening meal on six days each week. The practice is not an adequate substitute for sanitation.

TREATMENT OF THE ACUTE ATTACK

The attack on the schizogonous cycle of the parasites constitutes the specific therapy of the active infection, and for this purpose the civilian practitioner is now practically limited to totaquin and atabrine dihydrochloride. From the standpoint of their parasitocidal action the properties of the two drugs are closely parallel, and there is little choice between them, but effective concentrations in the plasma are built up more rapidly in the case of the cinchona alkaloids. The assault on the schizogonous cycle should be directed to two objectives. The first is the treatment of the acute attack, by which it is sought to reduce the parasitemia to such low levels that a clinical remission results. An acute attack may be the manifestation of a primary infection, a recrudescence, a relapse or a recurrence. This is usually readily accomplished. The second should be the eradication of the infection from the human host or the accomplishment of a cure. This requires treatment of the latent infection. With available drugs this result is highly uncertain, and under

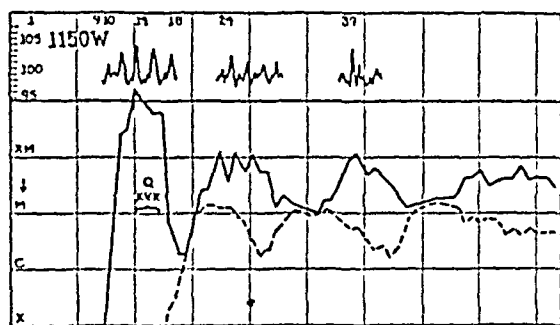

Chart 6.—Naturally induced falciparum infection in a white patient. Prepatent period ended on 9th day, incubation period ended on 10th day. Density of parasitemia exceeded 100,000 parasites per cubic millimeter on the 14th day, necessitating administration of single 0.6, 0.3 and 0.6 Gm. doses of quinine on the 14th, 15th and 16th days to control its exuberance. It is not apparent that these contributed to the drop in parasite density on the 18th day, coincidentally with the appearance of gametocytes. It should be noted that each period of clinical activity is attributable to a wavelike rise in the trophozoite parasitemia and that the density of trophozoites fell off with the appearance of gametocytes, each resulting in a spontaneous remission in the attack. During the period of observation, each of the first three trophozoite waves has been followed by a wave of gametocytes, which reached their maximum during the remissions.

ordinary circumstances success is not readily demonstrable.

Certain general principles should be observed in the employment of plasmodicidal drugs. Oral administration is always the route of choice, and the occasions when parenteral administration is required are unusual. Absorption from the stomach is so rapid that no material time is saved by parenteral administration. Parenteral administration should be limited to comatose patients or those with hyperpyrexia or in whom vomiting has proved uncontrollable. If parenteral administration is required, atabrine rather than quinine should be the choice, and the intramuscular rather than the intravenous route should be selected. It should, however, be mentioned that quinine dihydrochloride is still available for parenteral therapy. Injection should be made deeply into the gluteal muscles of both buttocks at a point about 3 inches below the iliac crest, with subsequent thorough massage of the site. Such an injection may be repeated after twelve hours but should not be continued after the patient can take medication by mouth.

The dosage of the drug employed must be adequate and should be initiated as soon as practicable after diagnosis is effected. Certain strains of *P. falciparum* appear to require larger doses to effect a satisfactory response, but I am skeptical that a parasite strain is likely to acquire a drugfastness. Differences in the strains of parasites prevalent in various regions probably account for divergences in reaction to treatment. While in general totaquin, like quinine, should be administered before meals and atabrine after meals, one of the daily doses should be scheduled to be given about one hour before the occurrence of the next anticipated paroxysm in order that a maximum plasma concentration may be available when the young merozoites are liberated. It should not be expected that the initiation of treatment will forestall the next anticipated paroxysm, or even the one due on the following day, but if treatment is adequate and the drug is properly absorbed, paroxysms should not occur on the third and subsequent days. It is helpful to control the effect of the drug by daily parasite counts. If quinine has been employed, only exceptional patients will show a few parasites, other than falciparum gametocytes in smears taken on the fifth day after treatment was initiated. If atabrine was administered, a few patients may exhibit parasites as late as the seventh day. During these periods the counts on successive days should exhibit a progressive decline. If these conditions are not soon met, it should be ascertained whether the patient is absorbing and excreting the drug, by applying appropriate tests to the urine. While not incompatible, nothing is gained by undertaking to administer the two drugs concurrently.

Totaquin (totaquina) is a preparation originally developed under sponsorship of the Malaria Commission of the League of Nations in order to supply a cheaper effective antimalarial drug through the utilization of all the alkaloids from cinchona barks the quinine content of which is too low for the profitable extraction of that alkaloid alone.¹⁷ Under present circumstances this is the most efficient manner in which to employ the limited stocks of American barks, which are the only supply available, and utilize the parasitocidal properties of the other crystallizable alkaloids of cinchona which have heretofore been largely ignored, although they are just about as effective plasmodicides as is quinine.¹⁸ The preparation as standardized in accordance with the U. S. P. XII contains not less than 7 nor more than 12 per cent of anhydrous quinine, and a total of not less than 70 nor more than 80 per cent of the anhydrous crystallizable cinchona alkaloids, the latter term including quinine, quinidine, cinchonine and cinchonidine.¹⁹ It should be prepared in friable tablets or placed in capsules for administration by mouth and should be administered in doses corresponding to those of quinine sulfate. It should not be given in fluid mixture. Totaquin is not available for parenteral administration. It is probably as inadvisable to administer totaquin to a pregnant woman as it would be to administer quinine. Totaquin should be administered to adults in divided doses in not less than 0.6 Gm. (10 grains) daily per 50 pounds (23 Kg.) of body weight.

19. Weed, L. H.: Critical Antimalarial Problem and Its Solution, J. A. M. A. 120: 1043-1044 (Nov. 28) 1942.

For an adult of 150 pounds (68 Kg.) this is the equivalent of 0.6 Gm. or 10 grains three times a day. Adult dosage may be given to all over 12 years of age. Dosage for children should be reduced in proportion to their age, while a baby may be given at least 0.06 to 0.09 Gm. (1 to 1½ grains). Field²⁰ considers that children should be given proportionately large doses. Doses should be given before meals and continued for seven days.

Prior to the last decade it was commonly recommended that a daily ingestion of 0.6 Gm. of quinine be continued for eight weeks after the acute attack was brought under control, in the belief that relapses were largely avoided thereby. It is doubtful whether many patients can be depended on to continue such protracted medication, while the convenience of the short period required for a single course of atabrine has tended to stimulate a curtailment in the period over which quinine is now frequently administered. The concurrent administration of plasmochin 0.01 Gm. thrice daily after meals is, however, considered a desirable adjuvant in the treatment of vivax infections, as lessening the likelihood of a relapse. Absorption of some of the cinchona alkaloids at least is rapid, excretion of quinine being detectable within fifteen to twenty minutes after the administration of a dose. Excretion is detected by the application of Tanret's test to the urine.²¹ While tinnitus and deafness may be an inconvenience to the patient, they are reassuring evidence of absorption. If the other cinchona alkaloids behave similarly to quinine, it may be assumed that the greater quantity is disintegrated in the body and that such slight stores as have accumulated are fully depleted within seventy-two hours after the last dose of a course is taken.

Atabrine dihydrochloride, or quinacrine, is an acridine dye developed in 1930 by Kikuth with the collaboration of Mietsch and Mauss. It is available in 0.1 Gm. tablets. Prior to our entrance into the war the complete synthesis of atabrine in the United States was not practiced. In view of the critical quinine situation it is fortunate that American chemists have succeeded in its synthesis and that large scale manufacture is now under way. Extensive chemical, pharmacologic and clinical studies have demonstrated that the American product is in all respects identical with the German drug.²² It has now been admitted to the United States Pharmacopeia under the name "quinacrine."

While most persons tolerate the doses recommended, a few may not support without discomfort even the mild regimen of suppressive treatment. These complain of headache, dizziness, nausea and vomiting, and diarrhea. These reactions are avoided by the concurrent administration of alkaline or sweetened beverages. Less frequently the drug has been reported to have produced a definite slowing of the respiration and cerebral excitation which may even attain maniacal proportions.

Atabrine is usually administered to adults after meals, one 0.1 Gm. (1½ grain) tablet being given three times (four times to large adults) a day for five days, or at least until four days have elapsed since the last fever. Children under 1 year may tolerate a total daily dose of 0.05 Gm., from 1 to 4 years of age 0.1 Gm., from 5 to 8 years 0.2 Gm., and those over 8 may be given a daily

total of 0.3 Gm.²³ These fractional doses are best given in milk.

In order to accelerate the action of atabrine by more quickly building up an effective plasma concentration, it is now recommended that adults initially receive 0.2 Gm. (3 grains) by mouth every six hours for five doses, which is thereafter reduced to 0.1 Gm. (1½ grains) three times a day for six days. The early elevated doses are accompanied by 1 Gm. (15 grains) of sodium carbonate in 200 to 300 cc. of water, sweetened tea or fruit juice.

For parenteral administration a dose of 0.2 Gm. may be dissolved in from 5 to 10 cc. of sterile distilled water. The effect of atabrine is not exerted as rapidly as that of quinine, a difference attributable to notably slower absorption, although urinary excretion is detectable within a few hours. Neither is its excretion as rapid, and the drug tends to accumulate, so that excretion continues for five weeks or more after the termination of a course. This may be the chief advantage of atabrine over quinine. Its excretion in the urine may be verified by the method of Wats and Ghosh.²⁴ For this reason courses of atabrine should not be repeated in less than a month's time. The small margin of safety between the therapeutic and toxic doses is probably related to the rapidity with which the blood level is raised and makes

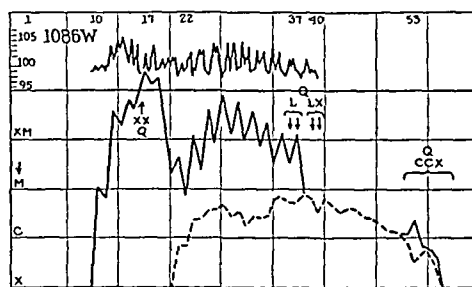

Chart 7.—Naturally induced falciparum infection in a white patient. Prepatent period ended on 10th day, incubation period on 12th day by a period of remittent fever lasting five days and changing to an irregular intermittent, which later became tertian, exhibiting prolonged paroxysms with bifid peaks suggestive of a quotidian. On the 17th day the parasitemia density exceeded 200,000 per cubic millimeter, when two 0.6 Gm. doses of quinine were given. This effectively restrained the exuberance of the parasitemia. The parasitemia was declining the day before gametocytes were first noted, but the decline was insufficient to produce a clinical remission, although the coincidental paroxysms were notably weaker. With the return of the trophozoites the counts on successive days oscillate widely. The attack was terminated by a total of 3.3 Gm. of quinine on the 37th and 38th day and a total of 4.0 Gm. on the 40th and 41st. Note the resistance of the gametocytes to these doses. Evidently the gametocyte waves which corresponded to the two trophozoite waves have fused. On the 53d day there began a seven day course of quinine, during which 14 Gm. of quinine was given.

it essential to avoid overdosage and the development of accumulations which may reach toxic levels. As the drug accumulates the patient may exhibit a yellowish discoloration of the skin, which should not be mistaken for jaundice but is a manifestation of its dye property. Plasmochin should never be concurrently administered, as gastric complications, pain and loss of appetite may occur.

Although intravenous therapy is counseled against, occasions may arise when it is considered imperative. It should not be continued after medication can be taken by mouth. The dose should be well diluted in at least 200 cc. of sterile saline solution and at least twenty minutes allowed for the injection. In the case of quinine particular care should be taken to see

that the needle is in the lumen of the vein. Fifteenth Gm. ($7\frac{1}{2}$ grains) of quinine dihydrochloride, or 0.2 Gm. (3 grains) of atabrine may be given as a dose to an adult. To the quinine solution may be added 0.5 to 1 cc. of a 1:1,000 solution of epinephrine hydrochloride. Neither drug should be given more than twice in twenty-four hours. One should guard against collapse.

In an effort to effect still further economies in the consumption of cinchona alkaloids and permit the patient to benefit from both the more rapid action of these alkaloids and the delayed excretion of atabrine, it is now recommended²⁵ that they be employed consecutively but not concurrently, as was early suggested by Dargan²⁵ as follows: Give totaquin or quinine as previously suggested for two or three days or until the paroxysms are suppressed, then change to atabrine as previously suggested for five days. If plasmochin is indicated, its administration should await the completion of a five day rest period.

In those falciparum infected patients with a parasitemia exceeding 500,000 parasites per cubic millimeter the prognosis to ordinary therapy is, as has been said,

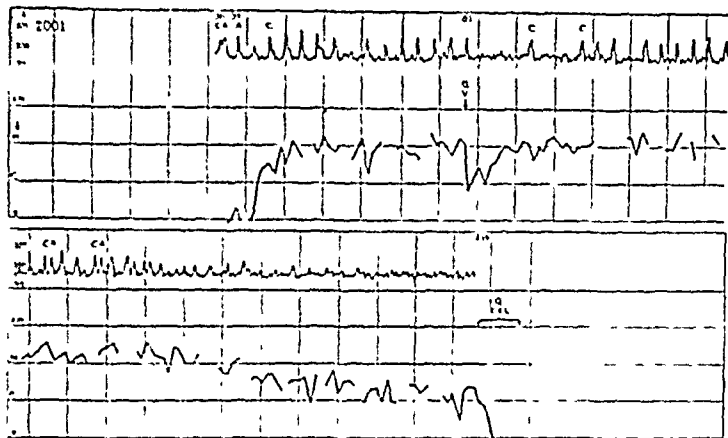

Chart 8.—Naturally induced quartan infection in a white patient. The incubation period required thirty-six days and the prepatent period required thirty-nine days. The onset presented a remittent fever for thirty-six hours and, subsequent to the intermission, changed to a simple quartan intermittent. On the 81st day the administration of 5 grains (0.3 Gm.) of quinine produced a remission lasting eleven days, owing to a depression in the parasitemia. Some irregularities occurred before regular quartan periodicity was restored, and still later a few double quartan paroxysms were noted. Except during the latter period, when some counts slightly exceeded 3,000 per cubic millimeter, very few counts at other times exceeded 2,000 per cubic millimeter. With a gradual spontaneous decline in the parasitemia, the paroxysms diminished in intensity and insensibly ceased. Subsequently 9.3 Gm. of quinine was given in divided doses over eight days.

bad. It is suggested that in addition to the routine therapy these patients may benefit from the mechanical removal of parasites by copious bleeding, the patient at the same time receiving a transfusion of an equal volume of blood from a compatible donor. The amounts removed should be large, totaling a liter or more of blood in twenty-four hours in one or more venesections.

Recrudescences, relapses and recurrences should be treated as suggested for primary attacks. It is frequently difficult to differentiate these from new infections. In some instances differentiation is possible. Thus, if at the clinical onset the parasitemia density is low and enlargement of the spleen is not detectable, a new infection is to be inferred. If on the other hand at the onset the density of parasitemia is appreciable, perhaps even as high as four or five thousand per cubic millimeter, and the spleen is enlarged, one is probably dealing with reactivation of a previously latent infection.

GAMETOCIDAL THERAPY

Patients with vivax or quartan malaria who are receiving adequate therapy with totaquin or atabrine will have the gametocytes destroyed along with the trophozoites and hence are soon noninfectious. However, those falciparum patients with mature gametocytes still remain infectious while taking adequate doses of these drugs, as the sexual forms are for some reason resistant. Plasmochin, a quinoline derivative, has little action on trophozoites of any species but possesses the unique property of devitalizing the infecting stage of the falciparum parasites, thus making the patient who receives it noninfectious. This constitutes the greatest field for the use of plasmochin. For this purpose it is given in 0.01 Gm. doses three times a day concurrently with each dose of quinine or totaquin during the last five days of the seven day course, or in the same amounts and for the same period, but subsequent to a course of atabrine, an intermission of five days being allowed between the two series. It should be administered after meals. Overdosage with plasmochin will result in the formation of methemoglobin, and the patient will appear cyanotic and may also complain of abdominal pain, sweating or cardiac symptoms. Consequently its administration should be under supervision.

TREATMENT OF LATENT INFECTIONS

Infections may be considered latent (a) immediately after therapeutic intervention has produced a remission in an acute attack and (b) when parasites are discovered on routine smear examination of an afebrile patient. Such patients often exhibit an anemia and splenomegaly and may find considerable inconvenience from the enlargement of this organ. As long as a patently latent infection is existent it should be borne in mind that recrudescences in falciparum malaria and relapses and recurrences in vivax and quartan malaria are a possibility. While in general unpredictable, yet in vivax infections they unquestionably occur more frequently in the spring. Persons with latent infections may have subclinical rises in their parasitemia and become transitorily infectious and are probably the principal if not the sole factor in maintaining the endemic from one season to the following.

Since the ultimate extinction of a malaria infection probably is more attributable to the activation of the body's immune mechanism than to the administration of the drugs under discussion, the physician faces a problem. Should treatment be protracted in the hope that relapses and recurrences will be prevented or should it be withheld in the expectation that, if there is a renewal of clinical activity, active treatment will be resumed? Opinions will differ and the last word cannot yet be said. In the event that protracted therapy during an induced remission or the treatment of a latent infection is considered indicated, successive courses of atabrine and totaquin should be alternated. In such an event atabrine given as previously described for treatment of the acute attack is administered as the first course, which without delay is followed by a course of totaquin and plasmochin also given as described except that the period over which it is administered is expanded to fourteen days. Each dose of totaquin may be reduced to 0.3 Gm. (5 grains). If further treatment is desirable the courses are repeated, but a rest period of perhaps ten days should intervene between the last day on which totaquin was given and the first day on which the second course of atabrine is begun.

25. Dargan, P. A.: The Therapeutics of Malaria, Indian M. Gaz. 69: 117, 1934.

If splenomegaly is persistent, Ascoli and Diliberto²⁶ advocate the intravenous administration of a protracted course of epinephrine. They begin with 0.01 mg. given daily or on alternate days if the reaction is intense. When any dose is finally supported with little reaction it is gradually stepped up in 0.01 mg. stages until 0.1 mg. is finally given. This is repeated twenty or thirty times until the spleen subsides, which usually happens in about two months. The reaction to the dose is immediate, the patients manifesting pallor, headache, tremors, sometimes psychic and motor excitation, and palpitation.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. DYER, DRs. HARDY AND
WATT AND DR. BOYD

DR. JOSEPH S. D'ANTONI, New Orleans: I am in complete agreement with the substitution by Drs. Hardy and Watt of the definite term shigellosis for the indefinite term bacillary dysentery. The change is logical from the standpoint of etymology and is further justified by the infrequency of dysentery of *Shigella* origin. I prefer, however, to distinguish more clearly than do the authors between diarrhea and dysentery, because of the possible end results of the two conditions. Whenever dysentery has been present there is a stronger likelihood of permanent bowel dysfunction. A diarrheic stool is a watery stool of fecal composition. A dysenteric stool consists of mucus, blood, cellular debris and pus, the passage of which is always associated with tenesmus. Diarrhea may or may not be interpreted by the patient as an abnormality of intestinal function. Dysentery would be considered abnormal by all patients, regardless of their usual bowel habit. The patients' interpretation of diarrhea and dysentery leads to the question of how many persons with such intestinal disorders consult the physician. A surprisingly large number with diarrhea do not. Of the 380 positive passive carriers of *Shigella* identified by the authors, only 2 were under the care of a physician, although 38 presently had diarrheal symptoms and 89 were convalescent. One of the group, indeed, was so ill that he died within three days of the survey. One might suppose that any patient with dysentery would seek medical aid at once, but, incredible as it seems, I recall a case of chronic amebic dysentery in a 55 year old Negro who had had from eight to ten bloody stools daily for three years. He claimed that he had not previously come to the hospital, a distance of 3 miles, because he knew he would have to defecate along the way. I am not in complete agreement with the usual impression that passive carriers of *Shigella* exhibit no clinical symptoms. My experience is that many patients considered as psychoneurotic, who complain of various gastrointestinal symptoms, with or without diarrhea, low grade fever and migratory polyarthritides, frequently, when properly investigated, are found to be suffering from shigellosis. Many of them, if questioned, can recall a previous history of dysentery, and most of them can recall a previous history of diarrhea, though it is true that similar histories might be obtained in any similar selected group of patients. In some cases which I have observed I have identified the same species of *Shigella* in both the earlier and the later illness, although in the interim the stools were negative and cure had been presumed. The authors' emphasis on repeated stool examinations in shigellosis is entirely correct. My own experience has been that an average of five cultures (using five differential mediums) may be necessary before a diagnosis can be made. It is important to emphasize the necessity of a thorough investigation of all patients with diarrhea who consult the physician. In *Shigella* infections the diarrhea in the majority of cases is mild and seldom lasts more than three or four days, yet the infection persists long beyond this time. The diagnosis of epidemic diarrheal disease, as the authors point out, is the joint responsibility of the practicing physician and the health officer, and the characteristics of the epidemic furnish the first clue to diagnosis.

DR. JOSEPH FELSEN, New York: Some idea as to the prevalence of bacillary dysentery may be gained by the fortyfold increase of reported incidence in 1941 as compared with 1933; and the reported incidence is but a fraction of the actual incidence. Diarrheas secondary to primary extraenteric infections are best termed "focal nonspecific enterocolitis," the pathway of bowel involvement being through the indirect hematogenous excretory mechanism. Most positive cultures in acute bacillary dysentery are obtained during the first three days, regardless of the degree of severity. When diarrheal cases in the United States are studied as a group, most of them appear to be bacillary dysentery. Carriers in this disease are "sick" carriers, as revealed by thorough clinical study, including sigmoidoscopy. There is a characteristic three stage progression of pathologic change: punctate follicular hyperplasia, punctate follicular necrosis, and discrete and confluent ulceration on the first, second and third days respectively. These are easily recognizable in the living patient by means of the sigmoidoscope, irrespective of the severity of the disease. The weakest links in the dysentery problem have been the educational and clinical. Prompt isolation, control of food handlers and education of the physician and layman are of paramount importance. Public health officials are concerned with statistical, epidemiologic and bacteriologic studies rather than thorough clinical investigation. A tabulation of epidemiologic data, strains and symptoms is no substitute for careful sigmoidoscopy and clinical acuity. Physicians must learn how to recognize the disease before they can report it. For this reason a clinical classification into the typical and atypical forms (afebrile, asymptomatic, constipated, appendicular, pneumonic, agranulocytoid and meningitic) is most important. Infectivity bears no relationship of severity. In fact, atypical or subclinical forms are often chiefly responsible for the spread of the disease. The Dysentery Registry has proposed as part of its educational program the formation of public health diagnostic teams composed of a suitably trained clinician, bacteriologist and public health worker. I have found sigmoidoscopic crypt aspiration cultures most effective, using a fresh Endo or SS medium. The sulfonamide drugs are a distinct advance but no panacea for bacillary dysentery. More recent advices received from civilian and military sources reveal an increasing number of recurrences and of carriers following the use of the sulfonamides. The absorbed drugs appear to be more effective than those which tend to remain local, the latter being rare in the ulcerated bowel. I again urge vaccination as a prophylactic measure, using endemic strains. Hardy and Watt also noted the protection afforded by a previous attack against subsequent infection with the same strain.

LIEUT. COL. THOMAS T. MACKIE, M. C., A. U. S.: Clinical similarities have rendered classification within the group difficult in the past, and it is only since the application of more exact immunologic methods that the distinction between the four major groups has become evident. Today a sharper distinction may be drawn between the three diseases in the typhus group: European or epidemic typhus, murine or endemic typhus and Brill's disease, and further that Brill's disease and murine typhus are distinct entities. Zinsser, on epidemiologic grounds, originally advanced the theory that Brill's disease represents a recrudescence of an old attack of European or epidemic typhus fever. Recently Plotz, investigating the complement fixation reaction, using unabsorbed and absorbed serums from a group of cases of Brill's disease has obtained strong confirmatory evidence indicating different antigenic patterns in the endemic and epidemic rickettsias respectively. It appears now, therefore, that Brill's disease is in fact a response to the epidemic or European strain in an individual already partially immune from a previous attack of European typhus and that these cases both etiologically and epidemiologically are distinct from the endemic or murine typhus. As Dr. Dyer points out, only two of these diseases, epidemic typhus and tsutsugamushi or Japanese river fever, have military importance. The wide distribution of the latter disease in Southeast Asia and the islands of the Southwest Pacific suggest that it may be a factor in military operations in those areas. Rocky Mountain spotted fever, however, has more immediate interest for the United States in view of its already wide distribution. The investigations on which this classification is

²⁶ Ascoli, M., and Diliberto, U.: Therapy of Chronic Malarial Splenomegaly. *South. M. J.* 25: 647-649, 1932.

based give promise of the ultimate development of additional methods of control for the entire group of rickettsial diseases, since the identification of immunologically different species constitutes the initial step in the exploration of immunizing vaccines.

BRIG. GEN. JAMES S. SIMMONS, U. S. Army: Rickettsial diseases are actually worldwide in distribution. It is highly appropriate to consider them in a symposium on tropical diseases. At the same time it should be emphasized that their greatest prevalence and most devastating outbreaks have occurred in the more northern regions of the world. Realization of the hazard of typhus to military personnel and civilian groups in war areas and possibly in this country was the basis of the conferences held in the Office of the Surgeon General in August 1942. One important outcome of these conferences was that the President, by executive order number 9285, dated 24 December 1942, established the United States of America Typhus Commission. The work of this commission under the Secretary of War is a joint enterprise of the Army, the Navy and the U. S. Public Health Service. Dr. Dyer has admirably summarized the progress that has been made in recent years in the differentiation of these diseases, in diagnostic methods and in measures for their control by prophylactic vaccination and by the application of new insecticides. There is little to be added to his remarks except by way of amplification from Army experience. The new type Cox vaccine appears to be highly effective. All troops going to typhus areas are vaccinated against typhus. Thus far there have been fewer than 50 reported cases of louse borne typhus in American troops. All these cases have been mild and there have been no deaths. Vaccination against typhus does not prevent infection, but it does modify the disease. The experience of the U. S. A. Typhus Commission accords with this. The advance in the discovery and use of new and effective insecticides has been great, particularly during the years of the war, since 1941. In fact the gains made by military applications of new insecticides against the vectors of insect borne diseases are certain to stand out as some of the most important contributions to the public health and welfare that have been made in recent years. Tsutsugamushi disease, "scrub typhus" or mite borne typhus, regarded formerly by workers in this country as a curiosity, has assumed great military importance because of its prevalence in the Southwest Pacific area and in the China-Burma-India theater of operations. Investigative teams have been sent to those areas to study the disease, its mode of transmission and the mite vector, and to find better methods of prevention. Dimethyl phthalate and other repellents have been found to be effective against *Trombicula*. Epidemiologic data have been collected from observations of troops in the field. Strains of the causative rickettsia have been brought back to this country for study in several laboratories. From the intensive investigations now being made on tsutsugamushi fever definite and beneficial advances are confidently anticipated.

Diseases Observed in Miners in the Sixteenth and Seventeenth Centuries.—Toward the close of the 16th century and during the early part of the 17th century scattered observations on certain diseases affecting miners had been made by various physicians. Gabriele Fallopius (1523-1562), in his treatise *De Metallis et Fossilibus*, noted that the workers in quicksilver mines suffer from mercury poisoning and that the majority of the miners remain at this work for barely three years. Andrea Mattioli of Siena, a contemporary of Fallopius, observed chronic mercurialism among the miners of quicksilver at Idria, in Carniola. Pieter van Forest (1522-1597) of Delft also made similar observations. J. B. van Helmont (1577-1644), the follower of Paracelsus, in his treatise on asthma and cough, *De Asthmate ac Tussi*, referred to a variety of asthma peculiar to miners and metal workers. According to Ramazzini, he described "a certain kind of asthma, between the dry and the moist species, which . . . is common among the diggers and refiners of metal, the minters of money, and such other workmen by reason of a metallic gas sucked in along with the air, and which stuffs up the vessels of the lungs."—Rosen, George: *The History of Miners' Diseases*, New York, Schuman's, 1943.

HEREDITARY SUSCEPTIBILITY IN RHEUMATIC FEVER

THE POTENTIAL RHEUMATIC FAMILY

MAY G. WILSON, M.D.

NEW YORK

At the present time rheumatic fever holds a prominent place in medical discussion and investigation. It is generally agreed that, although the nature of the disease is obscure, susceptibility of the host is the primary factor in the development of rheumatic fever. That this susceptibility is on an age and genetic basis is supported by considerable evidence.¹

For more than fifty years there has been a widespread clinical impression that heredity is a significant factor in the observed concentration of rheumatic fever in certain families. This belief was based in large measure on the observed familial incidence of the disease. Recent family studies have been in accord with this observation.²

Since familial concentration is commonly observed in contagious, dietary and parasitic disorders, a disease may not be considered hereditary on the basis of a high familial incidence alone. Nonhereditary factors must be excluded, and the operation of hereditary factors must be demonstrated by adequate genetic analysis. Genetic and epidemiologic studies have shown that the primary factor responsible for the familial concentration of rheumatic fever is hereditary susceptibility. In a series of rheumatic families studied it was found that the distribution of cases followed the general laws of inheritance. Furthermore, the frequency of cases was consistent with recessive mendelian inheritance.³

These studies were limited to a clinic population in New York City. They indicated that, if environmental factors such as climate, living conditions, diet or bacterial agents were responsible for the onset of rheumatic fever in susceptible children, they were uniformly operative and available. It was found that the number of age-genetic susceptibles estimated in every calendar year over a twenty year period of observation was in close agreement with the number of onsets observed. It was also demonstrated that the intrafamilial pattern of spread of rheumatic fever did not exhibit the usual characteristics of a communicable disease. One case did not constitute an obvious risk for secondary cases in the family. Age susceptibility appeared to determine the time of occurrence of cases in the family. It is important to emphasize that, although the number of genetic susceptibles estimated in these families was found to be in close agreement with the final number of cases observed, it cannot be concluded that every genetically susceptible child will necessarily develop rheumatic fever.³

The implications of these observations are apparent. The responsibility of the family physician, pediatrician, cardiologist and clinic is not limited to the medical

supervision of the rheumatic patient. A complete family history and adequate physical examination of every member of the family are advisable. When it is ascertained that one is dealing with a potential rheumatic family, instructions as to the nature of the disease and its protean manifestations should be given. Until specific preventive measures have been developed, potential susceptibles should be protected from all known predisposing factors which appear to play a role in the onset of the disease. Since the individual susceptible cannot be identified, all the children in a rheumatic family should be under medical supervision. In recessive inheritance eugenic principles are not applicable, unless perhaps in instances when both parents are rheumatic.

If susceptibility to rheumatic fever is transmitted as a recessive character, the chance for each child (in a family or group of families) to be susceptible may be expressed as follows: If both parents are rheumatic, nearly every child will be susceptible. If one parent is rheumatic and the other parent is nonrheumatic but a carrier, i. e. rheumatic fever is present among the immediate family, each child has a 50 per cent chance to be susceptible. If neither parent is rheumatic but both parents are carriers, each child has a 25 per cent chance to be susceptible. (If at least one child is rheumatic, it may be assumed that the negative parents are carriers.) If one or both parents are negative, i. e. definitely known to be nonrheumatic and noncarrier, susceptible children would be unlikely.*

The preceding figures may be used to estimate the number of genetic susceptibles present in a family when the genetic constitution of the parents with respect to rheumatic fever is known. If at least one child is known to be rheumatic, the number of genetic susceptibles present in a series of such families may be estimated. Genetic factors have been established which facilitate computation of the number of susceptibles present. It is merely necessary to tabulate the series of families according to family size and multiply each group of families of given size by the appropriate genetic factor. These estimates may then be compared with the actual number of cases of rheumatic fever present in the series.

It is generally believed that the incidence of rheumatic fever is lower in certain sections of the country and infrequent among children of the more favorable economic groups in all sections. Estimation of the role of certain environmental factors may best be made by using the family as the unit for genetic study. For example, if the mortality rates published by the Bureau of Census⁵ reflect the relative prevalence of rheumatic fever in various localities, it would be expected that in family studies in certain mountain states where the mortality rate is high there would be close agreement between the number of susceptibles estimated and the number of cases of rheumatic fever actually observed. Similarly, in the south Atlantic states, where the mortality rate is reported to be low, it might be expected that there would be a disparity between the number of susceptibles estimated and the number of cases observed. Such comparisons, made on data accumulated from different geographic locations and diverse economic

groups, should yield significant information as to the role of climate and environment in this disease.

Of practical importance is the opportunity afforded for evaluating preventive and therapeutic procedure by making a careful genetic selection of families. Since nearly all the children in families where both parents are rheumatic are probably susceptible to rheumatic fever, even a small series of such families would provide a critical experimental group for study. Recognition and observation of the potential rheumatic family offer a promising field for future research in rheumatic fever.

CONCLUSIONS

1. The responsibility of the family physician, pediatrician, cardiologist, clinic and school physician is not limited to the medical supervision of the rheumatic patient.

2. The potential rheumatic family should be identified and kept under medical supervision.

3. Studies of potential rheumatic families in different geographic localities and diverse economic groups should yield significant information as to the role of climate and environment in the development of rheumatic fever in susceptible individuals.

4. The public health approach to the control of rheumatic fever, like tuberculosis, may profitably begin with the potential rheumatic family.

CAUSE AND TREATMENT OF FURUNCULOSIS

PHILIP B. PRICE, M.D.

SALT LAKE CITY

The cause of furunculosis is obscure. External spread of bacteria from existing infections to nearby hair follicles is an obvious factor as many writers have pointed out, but that consideration alone does not account satisfactorily for the refractory nature of the disease and its tendency to relapse. Many other causes of furunculosis have been suggested, therefore, such as insanitary personal habits or surroundings, anemia, hypoproteinemia, debility, fatigue, low general or local resistance to the infection, hyperglycemia, low metabolic rate and internal foci of infection. Reflecting this uncertainty of causation, a host of therapeutic measures has been recommended and used for furunculosis, but not one of them has proved uniformly successful.

Certain characteristics of furunculosis point definitely to a local cause for the disease rather than to any systemic abnormality. Furunculosis usually starts with a single infection; thereafter boils tend to appear in succession and not simultaneously in a single crop, as might be expected in a blood borne infection. Furthermore, the individual furuncles invariably begin in hair follicles or their associated sebaceous glands. The lesions are nearly always limited to a region of the body, and extension of the involved area tends to be from the center of that region peripherally. When relapses occur, the infections appear as a rule in the original region. Organisms cultured from different furuncles in the same individual are identical. Not infrequently furunculosis occurs in previously healthy persons in whom no systemic abnormality can be demonstrated. Even during the height of furunculosis, blood culture is almost always negative. These con-

4. Because of the small size of human families the disease may not be expressed, even though the trait may be present in the family line. One might estimate the probable chance for a susceptible child to be about 3 per cent when one or both parents are negative.

5. Deaths from Acute Rheumatic Fever and Chronic Rheumatic Diseases of the Heart by Age and Race, Each State, 1941, Vital Statistics, Special Reports, United States Department of Commerce, Bureau of the Census, Aug. 18, 1943, vol. 17, No. 31.

*From the Department of Surgery, University of Utah School of Medicine.

siderations and a study of the bacteriology of the skin have led to the belief that a local spread of infection is sufficient to account not only for the features just listed but for the characteristic chronicity of the disease as well. Constitutional defects associated with furunculosis are thought to be contributory, secondary or coincidental.

It has been shown¹ that cutaneous bacteria are of two sorts, transients and residents. Transient or contaminating bacteria are loosely attached to the skin surface and are rather easily removed or killed. The resident flora, normally composed of bacteria of slight pathogenicity, is surprisingly stable; it may remain unchanged quantitatively and qualitatively for months or years. This resident flora can be removed or killed only with great difficulty. It is equally difficult to eradicate any particular type of organism which may be included in such a flora. In some way not fully understood certain contaminating bacteria, after prolonged contact with the skin, may change status and become residents. It is thought that, in furunculosis, discharges from the initial lesion carry infectious organisms to the surrounding skin and some of these pathogenic bacteria become incorporated into the resident flora of that region. There they live and multiply, perhaps without harm to the patient until by chance some of them are rubbed deeply into a hair follicle, whereupon a new furuncle starts. With each succeeding furuncle the skin of the region becomes more widely and heavily seeded with the offending bacteria. The fact that these organisms can become part of the resident flora, can live on the skin for long periods of time and are eradicated with great difficulty explains plausibly why furunculosis is so persistent despite local and systemic treatment, and why relapses so often occur in the original site.

Although metastatic infection in bones, kidneys and other distant points is not a rare complication of furunculosis, it occurs in a relatively small proportion of cases. It is probable that pressure, squeezing, incision or other trauma to furuncles produces a transient bacteremia, which in turn results in metastatic abscesses. In my opinion that is an exceptional mode of spread of infection in furunculosis, whereas the usual method of extension is by discharges, sweat, bathing and friction which smear the pathogenic organisms over the skin surface.

If the line of reasoning just presented is correct, rational treatment would consist primarily of an attempt to sterilize the skin of the whole contaminated region. If that could be accomplished, no new furuncles would occur. The word "sterilize" is used here advisedly, since there is reason to believe¹ that pathogenic bacteria in the resident cutaneous flora are no easier to remove or kill than the nonvirulent bacteria which usually predominate on the skin. Any such attempt to sterilize the skin should be carried out without injury to the tissues. And, if possible, subsequent contamination of the area with the same organism should be prevented.

Experimental studies² and abundant clinical experience prove that this desired effect cannot be achieved by application of iodine or other strong skin disinfectants. It has been found,³ however, that healthy skin can

be thoroughly degermed with a solution of ethyl alcohol exactly 70 per cent by weight. This particular preparation is a very efficient germicide which does not damage healthy skin even after long contact. Theoretical calculations, based on quantitative studies of skin disinfection, indicate that continuous application of this solution with gentle gauze friction for about twenty minutes will completely sterilize the surface of normal skin. Such treatment should not be used, of course, on open wounds, nor can it be expected to disinfect draining sinuses or hair follicles already deeply contaminated with a boil-producing organism. The optimum time to employ this treatment, therefore, is in the interval between the healing of the last furuncle and the onset of the next one.

In the last ten years many patients with furunculosis have been treated in the manner just described. Eleven of these cases have met the following criteria, and they form the basis of this report: (a) All 11 patients had true furunculosis; that is, a more or less continuous succession of deep-seated boils occurring over a period of several weeks or months. (b) All had been treated unsuccessfully by other methods. (c) All were treated personally by me in accordance with the principles outlined. (d) All were followed for two or more years after the alcohol treatment. In all the cases there was complete and usually sudden cure of the condition. And in none of them has there been any recurrence of furuncles during the period of observation.

REPORT OF CASES

The following case histories are typical:

CASE 1.—M. R., a woman aged 30, had been more or less incapacitated by boils on her legs for eight months. Many remedies, including vaccines, yeast, tin, x-rays, chemotherapy and various local applications, had been tried. The infections always began as deep-seated painful indurations, which worked their way slowly to the surface with almost no pus but with necrotic centers which eventually came away, leaving deep craters and relatively large scars. Each boil lasted two to four weeks. They occurred singly and in crops of three or four. Culture showed *Staphylococcus aureus*. The extremities were unusually hairy. There was no evidence of constitutional disease; the blood sugar and the basal metabolic rate were normal.

Seizing an opportunity when the latest boil had stopped discharging and no fresh ones could be seen, I washed both extremities from the hips to the ankles continuously for twenty minutes with freshly prepared 70 per cent (by weight) alcohol, using light gauze friction. The patient, followed for four years, had no further furuncles.

CASE 2.—M. C., a girl aged 10 years, had not been free from boils for over four months. The infections were scattered over the lumbar region, buttocks and backs of the thighs. Each boil began as a small, rather tender spot followed by a deep, painful induration, a necrotic head, a deep crater and slow healing. Many sorts of treatment had been tried without apparent benefit.

Utilizing a favorable opportunity when a crop of furuncles was subsiding, I placed the patient prone, the genitalia and anus were protected with a heavy coat of petrolatum and the entire infected area was washed with 70 per cent alcohol solution for thirty minutes. No more furuncles appeared, and the patient remained free from them thereafter for at least three years.

CASE 3.—R. C., a boy aged 9 years, had had boils in the region of the right knee for five weeks. When I first saw him 21 healing furuncles and recent scars were counted in an area of about 7 by 4 inches, and a crop of 6 new boils were starting, none of which had come to a head. The boy could not walk because of the pain.

An attempt was made to sterilize the skin at that stage in the manner already described, but evidently it became rein-

fects with discharges from the six new boils, for subsequently there were additional furuncles and superficial pustules. It was necessary to await a time when the active infections had subsided but before any new infections had started. Such an opportunity presented itself within three weeks. The area was then washed with 70 per cent alcohol for twenty minutes, and this treatment was followed by a complete and permanent relief.

CASE 4.—C. L., a man aged 32, had numerous painful furuncles on the neck, right cheek and chin for sixteen weeks. He had received several x-ray treatments besides local applications of various sorts, staphylococcus toxoid injections and a course of sulfonamide therapy. Zinc iontophoresis was used successfully for some of the infections near the lip.

The long stubble of beard was carefully trimmed away with scissors, and the region was washed gently with 70 per cent alcohol for twenty-five minutes. No more furuncles appeared, and the patient remained free from them for at least three years.

COMMENT

No claims are made for this method of treatment. The number of cases in which it has been used is too small to warrant any final conclusions as to its efficacy. My purpose in this communication is to present a rational theoretical basis for such a treatment together with the results which have been observed to date. It is hoped that wider use of the method will lead to an accurate assessment of its value.

It is important that the alcohol solution should be prepared properly if full disinfectant action is to be obtained. A full discussion of the important differences between percentages by volume and by weight, and directions for preparing 70 per cent alcohol by weight, have been published elsewhere.²

The germicidal action of alcohol on the skin is increased by friction, but in the presence of furunculosis rubbing is not without danger. Vigorous massage, particularly when directed against the normal inclination of hair shafts, may actually do harm by pushing live bacteria into hair follicles.

After prolonged application of alcohol the skin feels dry and may itch slightly. Patients should be cautioned not to rub or scratch the region. It is advisable to powder the disinfected area with sterile talcum or zinc stearate. Calamine lotion may be used in selected cases.

It is reasonable to suppose that in the production of furuncles infectious bacteria are first deposited superficially in hair pits, and that they are carried slowly toward the roots of the hairs by natural processes of reproduction and invasion, aided by rubbing, scratching and squeezing on the part of the patient.

I am among those who advocate nonoperative treatment of individual furuncles. Ordinary boils should seldom be incised even when fluctuation is observed but should be permitted to rupture spontaneously. Sinuses should not be dilated and drains should not be inserted. Evacuation of contents by pressure is both unnecessary and dangerous. The temptation to pick out a necrotic core is to be resisted. Cautics such as iodine and phenol applied to a furuncle or its surrounding skin are apt to do more harm than good. During the period of development furuncles may be treated with hot compresses, but they may do equally well if left strictly alone. Rest is important. Just before rupture a sulfathiazole paste dressing may be applied, and this treatment can be used to advantage during the period of discharge. I have had no experience with penicillin, aspergillin and allied compounds in the topical treatment of furunculosis.

It is too early to assess accurately the value of sulfonamides, or of penicillin and related compounds, in the systemic treatment of furunculosis. My impression is that sulfonamides have not been very successful when used for this purpose.

SUMMARY

Regional contamination of the resident flora of skin with boil-producing bacteria is postulated as the primary cause of furunculosis. With that as a working hypothesis a method of treatment has been devised which attempts to eradicate all the offending organisms from the involved area. Eleven patients with furunculosis so treated have had prompt and permanent relief.

OUTBREAK OF SEPTIC SORE THROAT DUE TO RECONSTITUTED POWDERED MILK

EPIDEMIOLOGIC OBSERVATIONS

LIEUTENANT RALPH F. ALLEN (MC), U.S.N.

AND

LIEUTENANT LOUIS S. BAER (MC), U.S.N.R.

It is well known that most epidemics of septic sore throat are traceable to contaminated raw milk. This, we believe, is the first such outbreak caused by milk from a contaminated "mechanical cow" to be recorded in the literature. As this machine is being widely used to supply our armed forces with fluid milk and ice cream, medical officers should be cognizant of the danger inherent in its improper operation.

CHRONOLOGY OF THE EPIDEMIC

The outbreak studied by us can best be visualized by referring to figure 2, which shows the total number of cases according to the date of onset of symptoms. A total representing approximately 10 per cent of the complement of the station were sick.

A careful inspection of the galley and food handlers was made when it became apparent that an epidemic was starting. Defects noted in the dairy room and preliminary case cards filled out on the first group of patients made it seem probable that milk was the source of the infection, and advice to discontinue its serving was given on the morning of September 30. A rapid subsidence of the outbreak followed compliance with this advice.

Further steps taken to control the outbreak were daily examination of all mess cooks, eliminating those with sore throats. The others were given 1.5 Gm. of sulfadiazine daily as prophylaxis against air borne spread of the disease. As further precaution against upper respiratory spread among the personnel at large, the swimming pool and movie were closed. No other measures were employed.

EPIDEMIOLOGIC EVIDENCE INCRIMINATING MILK

1. Air borne spread was ruled out by lack of correlation between place of work or sleeping quarters and incidence of sore throat.

2. The swimming pool was exonerated, for only 7 per cent of those sick had been swimming in the seventy-two hours preceding the outbreak.

Technical assistance was rendered by J. D. Andrews, PhM 1/c, D. A. Treat, PhM 2/c, J. R. Cook, PhM 2/c, and H. L. Oster, PhM 2/c. This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the U. S. Navy. The opinions and views set forth in this article are those of the writers and are not to be considered as reflecting the policies of the Navy Department.

3. The general mess was indicated as the source, because 100 per cent of the patients had eaten at the mess, whereas several large groups of personnel on the base eating at other messes were not sick.

4. Milk was the only article on the menu statistically significant. Of the first 100 patients admitted to the sick list, 100 gave a history of drinking milk. No other food could be similarly incriminated. Furthermore, inspection of the dairy revealed defects which could easily have allowed the serving of contaminated milk.

BACTERIOLOGIC EVIDENCE OF SOURCE OF INFECTION

A total of 155 throat cultures were made. When samples of these were cultivated on blood agar pour plates they proved to be practically pure cultures of

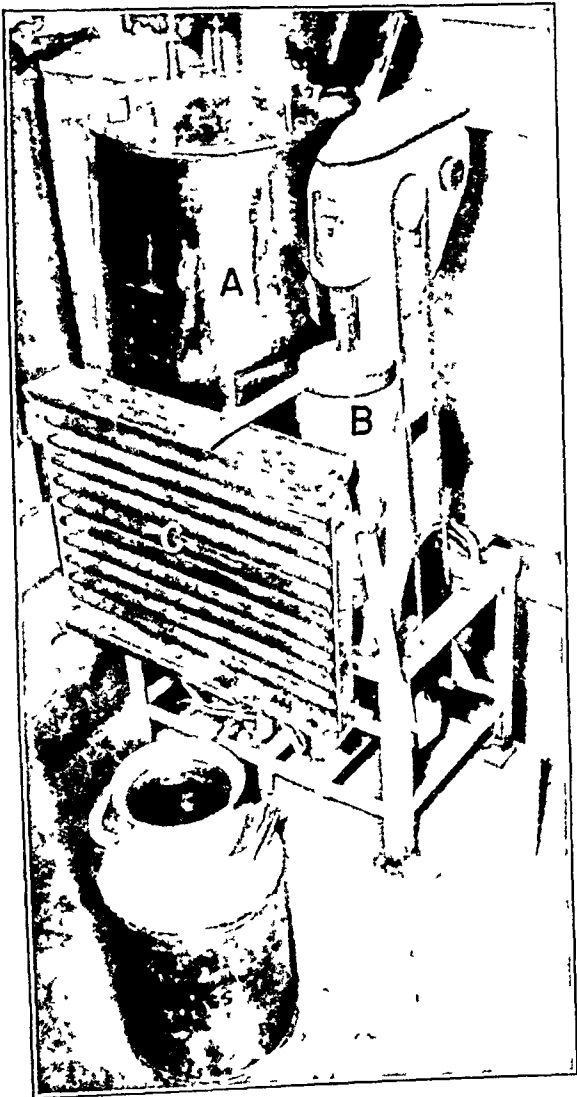

Fig. 1.—Design and operation of the mechanical cow, which is made in 10, 20 and 40 gallon sizes. The required amount of water is placed in the mixing tank (A) and heated to 80 F. by allowing live steam to enter the heating jacket surrounding the tank. Powdered dry milk is then sifted into the tank and the mixture agitated for five minutes. The temperature is then raised to 145 F. and held there for twenty minutes. Finally the required amount of sweet cream unsalted butter is added, the complete mixture is agitated for ten minutes while the temperature is kept at 145 F. and then the milk is passed through the high speed emulsifier (B). From here it is run over the cooler (C), the coils of which should be kept below 38 F. After cooling, the milk can be stored in a refrigerator until ready for use. The mechanical cow is manufactured by the United Dairy Equipment Company, West Chester, Pa.

beta hemolytic streptococci (fig. 3). Three of these cultures picked at random were further identified as belonging to group A as determined by the Lancefield precipitin method. Equipment for Griffith subtyping was not available. Cultures from the milk and scrapings from the mechanical cow showed beta hemolytic streptococci.

ULTIMATE SOURCE OF INFECTION

There were two men assigned to work in the milk preparation room. One of them gave a history of having had a sore throat and a tender swollen gland in his neck two weeks before the outbreak. He suffered a recurrence of his sore throat during the epidemic. In spite of the fact that his throat culture was positive for beta hemolytic streptococci, one cannot be certain of the nature of the organism causing his previous sore throat or whether or not he was a carrier.

RELATIONSHIP OF PREVIOUS TONSILLECTOMY TO THE MORBIDITY RATE

From the accompanying table it is apparent that there is a positive correlation between the presence of tonsils and one's chances of getting septic sore throat during the course of a milk borne

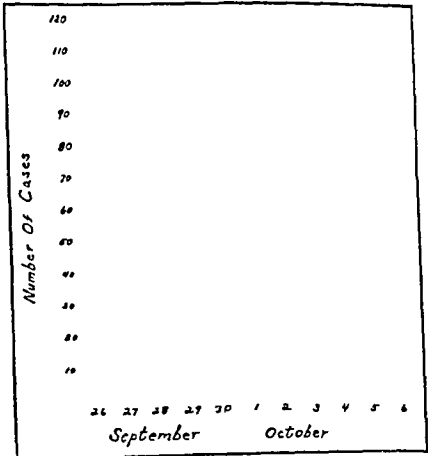

Fig. 2.—Morbidity totals by date of onset. Dispensing of milk was stopped on September 30.

Relation of Illness to Presence of Tonsils

	Sick	Not Sick
Tonsils in	77%	56%
Tonsils out	23%	44%

epidemic. The probability that such a distribution could occur by chance as calculated from the formula

$$X^2 = \frac{(ad - bc)^2 (a + b + c + d)}{(a + b)(c + d)(a + c)(b + d)}$$

is less than one in fifty.

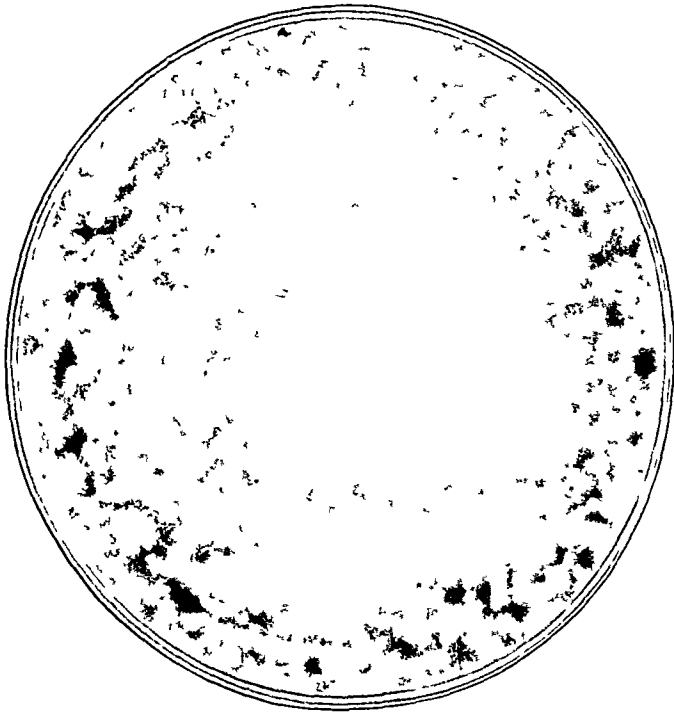

Fig. 3.—Culture of beta hemolytic streptococci

COMMENT

The chief value of an article such as this is to indicate a new source of danger to the health of military personnel and to recommend means of avoiding this danger

in the future. Based on our experience, the following suggestions are made for the benefit of medical officers at stations or on ships using the "mechanical cow."

1. Foremost in importance is careful instruction of enlisted personnel operating the machine and continued close supervision of their work.

2. Sufficient men should be assigned to the job and an adequate number of "mechanical cows" obtained to supply the needed quantity of milk without having to "railroad it through."

3. A thorough breakdown of the mechanical cow is necessary daily with careful scrubbing of all parts with alkaline washing powder followed by steam sterilization for at least one minute.

4. Weekly checks with a standard thermometer of both the pasteurizing and cooling temperatures is essential. A recording thermometer attached to the mixing tank of the mechanical cow is desirable.

5. Particular attention should be paid to keeping milk cans clean along the seams and prompt retinning of those that rust.

6. Careful screening and adequate ventilation are important and often overlooked items of sanitation.

7. Drying racks for the milk cans of approved construction are easily made and should always be used. Too often cans are placed upside down on the deck.

8. Bulkheads should be kept painted white to encourage cleanliness and expose dirt.

9. Frequent checks on the health of all milk handlers is an important duty of the medical officer.

Clinical Notes, Suggestions and New Instruments

DELAYED MORPHINE POISONING IN BATTLE CASUALTIES

MAJOR HENRY K. BEECHER
Boston, on leave

MEDICAL CORPS, ARMY OF THE UNITED STATES

Early in November 1943 a curious and, as it turned out, a common phenomenon appeared in the operating tents of the forward hospitals: On arrival in the receiving ward the wounded men, many of whom were in shock, all of whom were thoroughly chilled, appeared no different from other such patients. On receiving shock therapy and eventually becoming warmed up, many of these men developed profound respiratory depression associated with pin point pupils, yet neither sign had been present before resuscitation, nor had morphine been administered since arrival in the hospital.¹ These patients clearly appeared to be suffering from morphine poisoning. In the absence of head wounds it was difficult to attribute the condition to anything else.²

FACTORS LEADING TO DELAYED TOXIC EFFECTS

Consideration of the circumstances offered a probable explanation for them. In the first part of November it was cold in the valley of the Volturno. It rained, and snow fell low on the mountain sides. If a man was not wet and chilled before being wounded he soon became so after he fell, with the result that the circulation of his skin and subcutaneous region was greatly reduced if not altogether stopped.

The surgeon, North African Theater of Operations, U. S. Army, and the surgeon, Fifth Army, gave the author the opportunity to observe and report these findings.

Major Beecher is consultant in anesthesia and resuscitation, North African theater of operations; professor of anesthesia, Harvard Medical School, on leave, and anesthetist-in-chief, Massachusetts General Hospital, Boston, on leave.

1. A similar observation in civil practice (Cocoanut Grove Disaster) is described by Beecher, H. K., *Resuscitation and Sedation of Patients with Burns Which Include the Airway*, *Ann. Surg.* 117: 825, 1943.

2. Alcohol, chloral hydrate and barbiturates can produce signs similar to those of morphine poisoning but were unlikely complicating factors in the present circumstances.

It was not likely that morphine administered subcutaneously under these circumstances would be absorbed. Apparently it was not, for in many cases no pain relief occurred following its use, and the first dose of $\frac{1}{2}$ grain (30 mg.) of morphine would be followed by a second or even a third injection over a period of hours, all of these causing little if any effect. In the case of men in good general condition, warming alone with restoration of an active peripheral circulation caused the rapid simultaneous absorption of all the unabsorbed deposits of morphine; in some cases this occurred many hours after the injections had been made. In men in shock, restoration of blood volume and blood pressure, followed eventually by warming, with renewal of the peripheral circulation, led to the seriously rapid absorption of all the morphine injected, and poisoning developed.

In some cases it was necessary to undertake operation before full resuscitation from shock had been accomplished. Here, either would at first stimulate respiration and then, as the characteristic peripheral vasodilatation occurred, morphine injected many hours before would be rapidly absorbed with development of pin point pupils and profound respiratory depression, before the surgical stage of anesthesia had been reached. In such cases induction of anesthesia was prolonged to nearly an hour.³

FREQUENCY OF OCCURRENCE OF THE PHENOMENON

It is impossible to estimate with accuracy the frequency of occurrence of the phenomenon. The complication varies in its manifestations from the hardly perceptible to the fatal. It is often severe enough to be troublesome or serious clinically. In the first ten days of November the syndrome was recognized and pointed out in several hospitals. On the 11th of November it was discussed at the weekly medical meeting of the Fifth Army. Subsequently the phenomenon was everywhere recognized and commented on. It has been found to be a common and at times a serious complication.

It should be emphasized that, although cold weather certainly increased the likelihood of the development of the accident, low blood pressure, surgical shock or any other condition leading to or associated with reduced peripheral circulation presents the possibility for development of the syndrome regardless of the weather. The condition is one to be anticipated in civilian as well as in military practice.

CLINICAL IMPLICATIONS

The clinical implications are concerned with the avoidance of possibility for the development of the syndrome: Whenever possible morphine should be administered intravenously in small doses, $\frac{1}{8}$ grain (8 mg.) to $\frac{1}{4}$ grain (10 mg.). The full effect is thus achieved in a few minutes, and no possibility for delayed absorption exists. After fifteen or twenty minutes the dose can be repeated if necessary. As a practical matter morphine can rarely be administered intravenously on the battlefield: the extra time required, the necessity for speed, the numbers requiring treatment during heavy action, the frequently collapsed veins of the wounded, the unskilled personnel administering the agent, the poor physical facilities—all of these factors may combine to make necessary the continued use of peripheral injections of morphine. In such cases the injection is made intramuscularly (not subcutaneously) and is followed by massage. The site of the injection is low enough on an extremity so that, if signs of poisoning subsequently develop, a tourniquet can be placed above the morphine deposit in order to slow down the absorption rate. The site of the injection, in addition to the time and size of dose, should be recorded on the man's tag.

When any possibility exists that large unabsorbed deposits of morphine may already be present in a patient, further morphine necessary is administered intravenously in small doses. In such cases morphine is best avoided in preanesthetic medication.

TREATMENT

Realization that morphine intoxication may have a rather abrupt onset many hours after the last morphine injection, under the circumstances discussed, is a considerable help in recognizing the problem at hand. Correct diagnosis leads to prompt and effective treatment. A tourniquet, intermittently loosened, is placed proximal to the site of injection. Primarily the treatment

3. Among other cases, two going on simultaneously in the same operating room showed this sequence, although the last morphine had been injected respectively seven and nine hours before.

of morphine poisoning consists in the effective prevention of anoxia. This is best accomplished by oxygen administration with artificial respiration (if necessary), easily carried out with the aid of a closed anesthesia apparatus by means of intermittent bag pressure, with carbon dioxide absorption. Atropine $\frac{1}{60}$ grain (1 mg.) intravenously is probably of value. Ephedrine $\frac{1}{2}$ grain (30 mg.) intravenously has some value as a central stimulant. It will help to support a falling blood pressure. Hypertonic dextrose intravenously is a good diuretic and aids in excretion of morphine by the kidneys. Body heat should be conserved. If coma develops, a gastric tube should be inserted to eliminate the possibility of aspiration of gastric contents. Moreover, frequent change of position is of value in reducing later appearance of pulmonary complications. The treatment is supportive, while the morphine overdose is largely destroyed in the body.

SUMMARY

When the peripheral circulation is sluggish or inactive, as it may be in patients who are chilled or who have low blood pressure, subcutaneous injections of drugs are poorly absorbed. This was frequently observed to be the case in the Italian campaign. Subcutaneous injection of morphine under such circumstances fails to relieve the pain of wounded men. Repeated injections, sometimes over a period of many hours, are not absorbed until finally by shock therapy and warmth the circulation is reestablished in the skin and subcutaneous regions. The unabsorbed deposits of morphine, often totaling a grain or a grain and a half, are then taken up by the active circulation so rapidly that signs of morphine poisoning previously not present then appear, as shock is overcome.

It is usually stated that wounded men require large doses of morphine, doses that may be dangerously large. It is probable that this clinical tradition had at least part of its basis in poor absorption of the morphine in cases such as these. Although the intravenous use of morphine is desirable and would eliminate the problem, such use is not ordinarily practicable under field conditions. In this case, intramuscular injection followed by massage is the choice.

CLOSED REDUCTION OF FRACTURED LUMBAR SPINE WITH UNILATERAL DISLOCATION

LIEUTENANT COLONEL H. B. JENKINS AND MAJOR CHARLES L. NEILL
MEDICAL CORPS, ARMY OF THE UNITED STATES

Fracture dislocations of the lumbar vertebrae are rare. According to Frazier and Allen¹ the infrequency of lumbar dislocations may be attributed to a number of anatomic factors. Unlike the cervical region, where dislocations are most common, there is a comparatively limited range of motion in the lumbar region; the bodies of the lumbar vertebrae are much larger in every dimension; the intervertebral disks are thicker and more elastic; the ligaments at this level of the spine have great strength, and finally—what is probably a factor of greatest importance—the articular processes interlock. These authors have stated that with one exception in all cases dislocations of the lumbar vertebrae have been either backward or forward. In the exceptional case, reported by Schmid,¹ a rotary dislocation is seen in roentgenograms with the second, or proximal, vertebra projected to the right 1.5 cm. beyond the third, or distal, vertebra and the alignment of the spinous processes not disturbed.

In more recent literature Adams² reported a case of unilateral dislocation of the fourth on the fifth lumbar vertebra in which there was forward displacement of the spine at the level of the fourth. Attempted reduction by closed manipulation was unsuccessful, and open operation was necessary to correct the deformity. The patient was able to resume normal activities six months later.

A case of fracture dislocation was reported by Barber³ in which the first lumbar vertebra was displaced laterally on

the second and there was considerable anterior displacement. Open operation was necessary to secure reduction. Barber referred to a case reported by Rogers as the only other instance in which open surgical reduction had resulted in satisfactory recovery.

Fig. 1.—A, anteroposterior view on admission; B, lateral view on admission. Photo by U. S. Army Signal Corps.

A severe crushing fracture of the second and third lumbar vertebrae, with complete lateral and pronounced downward displacement of the first and half the body of the second, was reported by Gordin.⁴ There was little evidence of injury to the cord or to the cauda equina, but open operation was done in an attempted reduction, and fragments of lamina, spinous processes and other posterior fragments of vertebrae were removed to prevent eventual pressure of cord or cauda equina due to callus formation. This patient made an excellent recovery with a 2 inch (5 cm.) shortening of the spinal column and side to side union. Six months after injury he was back at work as a laborer.

Böhler,⁵ in discussing the treatment of fracture dislocations in the lumbar region, stated that dislocations in the lumbar region could be reduced only by traction or in a bloody way by resection of the processes.

REPORT OF CASE

H. T. T., a white soldier aged 23, native of New York, with eight months' army service, was injured on Aug. 16, 1942

Fig. 2.—A, anteroposterior view after closed reduction; B, lateral view after closed reduction. Photo by U. S. Army Signal Corps.

when thrown from a truck. He landed on his feet but was knocked down by and pinned beneath the truck, which had

2. Adams, A. Wilfred: Fractured Lumbar Spine with Unilateral Dislocation, *Brit. J. Surg.* 25: 632 (Jan.) 1938.
3. Barber, C. Glenn: Open Surgical Reduction of Fracture Dislocation of the Lumbar Spine with Cord or Cauda Equina Involvement, *Am. J. Surg.* 52: 238 (May) 1941.

overturned. On his admission to the station hospital, Camp Gordon, Georgia, about one hour after the injury, his blood pressure was 116 systolic and 78 diastolic, pulse rate 110, respiratory rate 24 and temperature 98 F. Small lacerated wounds were noted over the right supraorbital region and on the right leg. There was a contused wound over the right iliac crest. There was a complete flaccid paralysis and loss of sensation below the level of the fourth lumbar root distribution on both sides. Roentgen examination revealed a 2 cm. lateral displacement to the left of the fourth lumbar vertebra on the fifth, with fracture of the right inferior articular facet of the fourth and the right superior articular facet of the fifth (fig. 1). After six hours there was slight improvement of sensory function on the left side, but complete loss of motor and sensory function persisted on the right. Eighteen hours after admission there was no further improvement in neurologic function.

With the patient under ether anesthesia on the x-ray table eighteen hours after the injury was incurred, four-man counter-traction on trunk and lower extremities was used, while two-man lateral counterpressure was exerted on the trunk and pelvis, with the fluoroscope being used for observing the reduction. With this manipulation the fourth lumbar vertebra was readily aligned, and a plaster spica was applied from the upper part of the thorax to the hips (fig. 2).

The following day pronounced improvement in sensory and motor function was noted. The patient was able to move

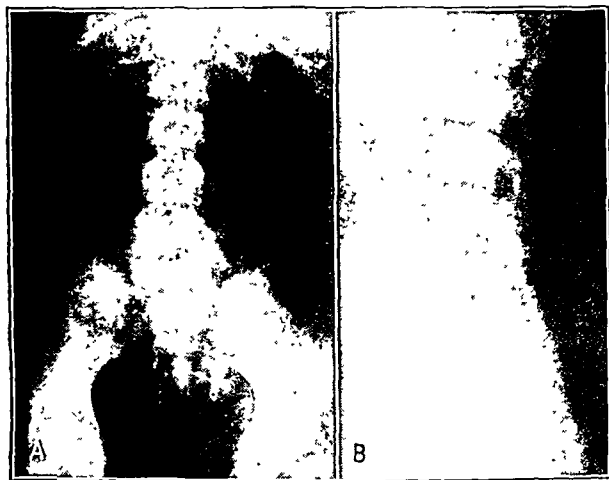

Fig. 3.—A, anteroposterior view five months after injury, B, lateral view five months after injury. Photo by U. S. Army Signal Corps.

both legs with good muscle power with the exception of the dorsiflexors of the right ankle. There was good touch sensation over both lower extremities, but pinprick sensation was dull over the lateral aspect of the right leg and foot. At the end of two months there were no residual sensory changes and the dorsiflexor muscles of the right ankle were functioning but still weak. There have been no further neurologic changes.

The patient was allowed to go home on a convalescent furlough of thirty days on Jan. 18, 1943, five months after his injury (fig. 3). He was discharged to duty on May 1, 1943, but owing to the weakness of the dorsiflexor muscles of the right foot he was reclassified to limited duty. He now walks without apparent limp, does not have any pain or impairment of movement of the back and has been on continuous active duty as a clerk in the hospital since his discharge as a patient.

SUMMARY

A case of unilateral fracture dislocation of the fourth on the fifth lumbar vertebra without anterior or posterior displacement and with injury to the cauda equina was observed. No similar case has been encountered in the literature. Closed reduction was effected by manipulation, and the patient has resumed his duties as a soldier. A great force is necessary to produce a dislocation in this region, where the structural support of ligaments, muscles and bone is the strongest of any region of the vertebral column.

Council on Pharmacy and Chemistry

REPORT OF THE COUNCIL

THE COUNCIL ON PHARMACY AND CHEMISTRY IS FREQUENTLY ASKED TO CONSIDER FOR ACCEPTANCE SOAPS WITH CLAIMED ANTI-INFECTION ACTION. USUALLY THE CLAIMS FOR BACTERIOSTATIC AND BACTERICIDAL VALUE ARE BASED ON SOME INGREDIENT INCORPORATED IN THE SOAP, OCCASIONALLY ON THE OILS AND FATS USED TO PREPARE THE SOAP. MOST OF THE EVIDENCE THAT HAS BEEN PRESENTED TO THE COUNCIL ON BEHALF OF EACH SUBMITTED ARTICLE HAS BEEN LACKING MANY DETAILS WHICH WOULD PERMIT ADEQUATE EVALUATION. WITH THIS THOUGHT IN MIND THE COUNCIL PROPOSED THAT A REPORT BE PREPARED TO PRESENT THE STATUS OF "ANTI-INFECTION" SOAPS WITH THE HOPE THAT IN THE PREPARATION CRITERIA WOULD BE SET UP FOR THE GUIDANCE OF MANUFACTURERS AND ALL OTHERS INTERESTED IN THIS SUBJECT. ACCORDINGLY, HARRY E. MORTON, Sc.D., DEPARTMENT OF BACTERIOLOGY, UNIVERSITY OF PENNSYLVANIA SCHOOL OF MEDICINE, HAS UNDERTAKEN AN EXHAUSTIVE REVIEW OF THE INFORMATION THAT IS AVAILABLE ON THE GERMICIDAL ACTION OF SOAPS AND HAS CARRIED OUT MUCH ORIGINAL INVESTIGATION; HIS FINDINGS ARE REPORTED BELOW. AT THE CONCLUSION OF DR. MORTON'S WORK DR. JOSEPH V. KLAUDER, PHILADELPHIA, MADE FURTHER STUDIES AND REPORTS THEM IN A DISCUSSION OF DR. MORTON'S INVESTIGATIONS. THE COUNCIL EXPRESSES ITS APPRECIATION OF THE ASSISTANCE PROVIDED BY DR. MORTON AND KLAUDER AND HOPES THAT THIS REPORT WILL BE OF SOME INTEREST TO, AMONG OTHERS, THE SURGEON, THE INDUSTRIAL PHYSICIAN AND THE DERMATOLOGIST.

AUSTIN E. SMITH, M.D., Secretary.

"GERMICIDAL" SOAPS

I. THE IMPORTANCE OF A CLEAN SKIN, THE ACTION OF SOAPS IN FREEING THE SKIN OF VIABLE MICRO-ORGANISMS, AND METHODS FOR TESTING THE EFFICIENCY OF GERMICIDAL (MEDICATED) SOAPS

The skin not only serves as a mechanical barrier to the entrance of micro-organisms into the body but, according to some investigators, also exerts a lethal action toward many bacteria. Arnold, Gustafson, Hull, Montgomery and Singer¹ in 1930 demonstrated that micro-organisms making up the exogenous bacterial flora of the skin, referred to by Price² as "transients," are readily destroyed by the skin. The destruction of those micro-organisms comprising the endogenous flora, or "residents," as Price² calls them, is not as great. The destruction of *Serratia marcescens* (*Bacillus prodigiosus*) by the skin on the backs of 13 healthy young adults varied from 89 to 99.7 per cent after an exposure of ten minutes. In addition to *Serratia marcescens*, *Escherichia coli*, *Eberthella typhosa*, *Salmonella enteritidis* and *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*) were readily destroyed by the skin on the palmar surface of clean hands; *Staphylococcus aureus*, *Staphylococcus albus* and *Staphylococcus epidermis albus* were destroyed more slowly. Colebrook³ likewise observed that hemolytic streptococci, *Proteus vulgaris*, *Klebsiella pneumoniae* (Friedländer's bacillus) and *Escherichia coli* rapidly decreased in number when applied to the skin of a finger.

Arnold and his associates¹ pointed out the importance of clean skin to the self-disinfecting power of the skin. They tested the hands of workmen (electricians and plumbers) before and after washing and cleansing their hands at the end of the day for the ability of the skin to destroy *Salmonella enteritidis*. Dirty skin had very little destructive action on the test organism, whereas, after washing the hands, there was rapid destruction of *Salmonella enteritidis*. In the study of hemolytic streptococci in normal persons and in carriers, Hare⁴ discovered the organisms on

4. Hare, R.: Haemolytic Streptococci in Normal People and Carriers, *Lancet* 1: 85-88, 1941.

the legs of 96 male students in only 7 instances. Of 16 persons who had no hemolytic streptococci on the skin of the legs, 4 acquired the organisms on an area of the skin purposely left unbathed, 3 during the first week and the fourth after the second week, thus emphasizing again the importance of cleanliness for the normal self-disinfecting power of the skin.

Yeast cells as well as bacteria were found to be removed from the surface of the skin by Cornbleet and Montgomery.⁵ Moist areas suffer a depression of their sterilizing powers, and areas with denuded epithelium are not as efficient as intact areas in removing yeasts and staphylococci.

Arnold and his associates¹ noticed that the self-disinfecting power of the skin varied somewhat with different regions of the body, as did Cornbleet and Montgomery.⁵ The skin in the nail region of the tips of the fingers was poorer in its self-disinfecting power than the skin on the palmar and dorsal surfaces. There was a slight but constant difference in the self-disinfecting power of the skin on the palmar and dorsal surfaces of the hand (Karns and Arnold⁶). Fisher⁷ reported that there was a decided drop in the self-disinfecting power of the skin on the hands of some women during the menstrual cycle.

Many workers have observed that micro-organisms, such as staphylococci, commonly found in the endogenous bacterial flora of the skin often increase in number during washing with soap and water. In a recent article Arnold⁵ states that the cornified layer of the skin behaves like a colloidal gel structure; increase in water content causes an increase in the surface endogenous flora, while dehydration is associated with a decrease in the viable bacteria. The flora returns to the normal density when the cornified layer readjusts itself. The endogenous bacterial flora can be increased by alkalinization and by exposure to warm water and to warm humid air. It can be decreased by exposing the skin to acid. A cornified layer with increased water content permits exogenous bacteria to survive for longer periods of time; a dehydrated layer rapidly renders the bacteria nonviable.

The only results at variance with the numerous works cited are those of Norton and Novy.⁹ The latter workers noticed that the number of bacteria (*Serratia marcescens*) rapidly diminished after application to the skin. The effect was particularly noticeable during the first ten minutes. Similar results were obtained with inert materials such as glass slides, filter paper and tanned hide. The authors concluded that the most important factor involved was moisture and that living skin did not show any inherent germicidal power. Colebrook³ attempted to rule out the effect of drying by making comparable tests with broth cultures of various organisms swabbed on fingers and test tubes. Colebrook's results show much less killing of the test organisms on test tubes than on fingers, but the conditions of the tests are not strictly comparable and more and better work could be done profitably concerning this important point.

II. THE ACTION OF SOAPS IN FREEING THE SKIN OF VIABLE MICRO-ORGANISMS

In addition to the esthetic reasons, it has been shown in the preceding section that cleanliness is important for the function of the apparent normal self-disinfecting power of the skin. Soap is usually employed in cleansing the skin because of the readiness with which it removes visible dirt. One of the methods by which soap acts as a detergent is the physical removal of foreign matter, including micro-organisms, owing to its low surface tension. In addition to this physical action, chemical actions may be at work as well. In 1925 Walker¹⁰ stated that the thorough washing of the hands with the formation of a good lather with any ordinary soap was sufficient to destroy any adhering diphtheria bacilli, streptococci and pneumococci. Typhoid bacilli were affected to a lesser extent, and *Staphylococcus aureus* possessed a pronounced resistance (Walker¹¹). The activity of the soap was greatly enhanced by raising the temperature.¹² Colebrook and Maxted¹² in 1933 found that *Streptococcus pyogenes* was very susceptible to the action of yellow household soap and that staphylococci and *Escherichia coli* were little affected. Meningococci and gonococci are highly susceptible to the germicidal action of soaps, Walker¹³ reporting *Neisseria intracellularis* killed in an exposure of two and a half minutes by 0.4 to 0.04 per cent solutions of soaps of the fatty acids ordinarily present in soap bases. *Neisseria gonorrhoeae* was killed under the same conditions by 0.04 to 0.006 per cent solutions of the same soaps. Phenol in 0.5 per cent solution was required under the same conditions. In 1931 Walker¹⁴ added influenza bacilli and *Treponema pallidum* to the list of micro-organisms susceptible to the bactericidal action of soaps and also reported that meningococci and gonococci were killed in an exposure of two and a half minutes at 20 C. by 1:640 dilutions of white floating soap, coconut oil soap, brown bar (laundry) soap, perfumed soap, Sapo Mollis (U. S. P.) and olive oil soap. The gonococcus was slightly more susceptible, being killed by dilutions of 1:1,280 of white floating soap and coconut oil soap. Colebrook and Maxted observed that refined toilet soaps and soft soap had much less bactericidal effect on *Streptococcus pyogenes* than yellow household soap.

Soaps prepared from pure fatty acids differed decidedly in their germicidal properties. There was no great difference in the actions of the sodium and potassium soaps of the same fatty acids.¹¹ Walker¹⁰ stated that the activity of coconut soap against the typhoid bacillus seems to be due to its high content of saturated fatty acids and to the very low proportion of unsaturated acids. In studying the germicidal action of the hydrogen ion and of the lower fatty acids, Cowles¹⁵ concluded that above p_H 2.6 the hydrogen ion concentration rapidly loses its germicidal power for *Staphylococcus aureus*. In the case of unbuffered lower fatty acids the germicidal action appears to be due to a summation of the effect of the hydrogen ion and of the undissociated molecule. In the case of the higher fatty acids the germicidal action against *Staphylococcus aureus*

appears to be due mainly to the undissociated molecule. Valette and Liber¹⁶ reported that the germicidal action of the sodium salts of lauric, linoleic and ricinoleic acids on *Staphylococcus aureus* depended on the degree of hydrolysis. When tested in buffered solutions at p_H 5.8, 6.4, 7.2 and 8.0, sodium laurate and sodium linoleate were most effective at p_H 5.8. Sodium ricinoleate was most effective at p_H 6.4. Considering the p_H of the buffered solutions, it may be inferred that the germicidal action of these compounds is due to the undissociated fatty acid molecule. Colebrook and Maxted determined that it was not the alkalinity of the soap which was responsible for the bactericidal action on *Streptococcus pyogenes*.

Aside from the ordinary detergent action of soaps due to physical actions, certain micro-organisms appear to be killed by the chemical actions of the soaps. It is quite logical to expect that an attempt would be made to incorporate certain germicides in soaps in order to make the soaps germicidal to a wider range of micro-organisms and perhaps in higher dilutions of the soap. As was pointed out by Hamilton,¹⁷ the incorporating of a germicide in a soap is not without practical difficulties because of the physical properties of the resulting mixture or of chemical reactions impairing the quality of one or both of the two agents. The use of mercuric iodide as proposed by McClintock¹⁸ in 1897 has been used for the longest time and appears to be the most effective germicide after incorporating in soap (Symes,¹⁹ Norton,²⁰ Colebrook and Maxted¹²).

III. TESTING SOAPS FOR THEIR GERMICIDAL ACTION

As a starting point, the general directions for testing antiseptics and germicides as set forth in Circular No. 198²¹ of the United States Department of Agriculture can be followed for technic, but advantage should be taken of improvements in culture mediums which have been made in recent years. In the case of soaps, changes must also be made in the period of exposure of germicide and test organism. The majority of the germicidal soaps contain mercurials which are known for exerting a very high bacteriostatic, rather than a bactericidal, effect. Shippen²² recommended transferring four loopfuls from each subculture to a second tube of subculturing medium. This was for the purpose of diluting, to a point where it was no longer bacteriostatic, the germicide transferred to the first subculture tube along with the inoculum. However, this procedure probably does not remove any mercurial compound which may be bound, loosely or otherwise, to the micro-organisms and which may be continuing to exert a bacteriostatic effect. Another possible fallacy of this technic is that after the micro-organisms have been exposed to the germicide for as long as fifteen minutes the number of viable organisms contained in a loopful of material may be so small as not to allow any to be transferred with the four loop-

fuls of medium from the first subculture tube to the second subculture tube. Also the amount of germicide attached to the bacterial cells might be sufficient to prevent their growth or at least to prolong the lag period beyond the required incubation period of forty-eight hours. This assumption is verified by the results of tests reported in table 1.

The medium proposed by Brewer²³ in 1940 for the cultivation of anaerobic micro-organisms was found also to have the property of destroying the bacteriostatic effect of mercurial compounds which might be present in materials as preservatives, thus preventing the mercurials from continuing to exert a bacteriostatic effect in the subcultures. Sodium thioglycollate medium has been made the approved medium by the National Institute of Health for the testing of biologic products since July 1, 1942. It cannot, however, be considered a universal medium, as McClung²⁴ reported that it was unsatisfactory for certain members of the genus *Clostridium*.

The usual precautions that each lot of medium support adequate growth of the test organism should be observed, and in addition it must be demonstrated that each lot of thioglycollate medium is capable of destroying the bacteriostatic effects of mercurial compounds. An inoculum of 1 to 4 cells of *Staphylococcus aureus* has been found to initiate growth in either extract broth or sodium thioglycollate medium. However, the incubation period of forty-eight hours as prescribed in Circular No. 198²¹ when using extract broth for the subculturing medium is not sufficient when employing the sodium thioglycollate medium. This may not be due to the medium being poor in growth promoting qualities but rather to the fact that thioglycollate medium contains 0.05 per cent agar to make the medium less fluid and reduce convection currents. When only a few viable organisms are present in the inoculum, growth takes place as small discrete colonies, in contrast to the diffuse turbidity which takes place in a tube of extract broth or other fluid medium. Tubes of sodium thioglycollate medium often do not show visible signs of growth until between forty-eight and seventy-two hours, and occasionally between seventy-two and ninety-six hours. Seldom have changes been observed after ninety-six hours of incubation, but they do take place, so it is desirable to incubate subcultures in sodium thioglycollate medium for one week.

Technic.—1. Sterile distilled water was employed in making all dilutions.

2. In the case of liquid soaps, a 5 cc. portion was transferred to the first medication tube and another portion was employed for preparing serial dilutions in the medication tubes. The total volume of soap or soap solution in each medication tube was 5 cc.

3. In the case of bar soap, thin shavings were made from the edge of the bar, weighed on an analytic balance and transferred to a sterile graduated cylinder with a ground glass stopper. Usually the soap shavings were dissolved and diluted to 25 or 50 cc. in a cylinder of 50 cc. capacity. To hasten solution the cylinders of soap solution were frequently placed in a 37 C. water bath for a short time before the serial dilutions were made up.

4. The tests were carried out at room temperature.

5. A twenty-four hour old culture of *Staphylococcus aureus* in extract broth p_H 6.8 was employed. It was maintained under conditions described in Circular No. 198. Five-tenths cc. was added to each medication tube.
6. Subcultures were made at intervals of five, ten and fifteen minutes with a 4 mm. platinum loop bent at an angle so that the flat surface of the loop was parallel to the surface of the fluid in the medication tubes when withdrawn. If a soap showed killing action in an exposure of five or ten minutes, it was retested at intervals of one-half, one, two, three and four minutes.
7. The temperature of incubation of subcultures was 37 C.
8. The duration of incubation of subcultures was one week.
9. The growth in critical tubes was checked microscopically and often by streaking onto appropriate medium.

- more advisable if only a few viable organisms are present.
- Interpretation of the Results in Table 1.*—1. Extract broth is not a satisfactory subculturing medium when testing soaps which contain a mercury compound.
2. The procedure of subculturing the material in the primary subculture tubes to a second tube of extract broth, as recommended by Shippen,²² is not satisfactory in destroying the bacteriostatic action of mercurial compounds.
3. Subculturing from the medication tubes directly into sodium thioglycollate medium is satisfactory, without making additional subcultures.
4. An exposure of the inoculum-germicide mixture to the action of sodium thioglycollate medium for fifteen minutes appears to be sufficient in the majority of cases to destroy the bacteriostatic action of the mercurial compound.

Tubes in columns A, C and E were extract broth and tubes in columns B, D and F were sodium thioglycollate medium used for subculturing the primary subcultures. These tubes were inoculated as follows: As soon as the standard phenol coefficient test was completed, 1 cc. from a primary subculture tube, after thorough mixing, was removed with a sterile 1 cc. pipet, 0.5 cc. transferred to a tube of extract broth, labeled either A, C or E, and the remaining 0.5 cc. transferred to a tube of sodium thioglycollate medium, labeled either B, D or F. After the contents of the tubes were thoroughly mixed, the tubes were incubated with the other tubes from the test. By employing the same time schedule as used for the phenol coefficient test and beginning immediately after completion of the test proper, the inoculum in each primary subculture tube was in contact with the subculturing medium for fifteen minutes. Sterile 1 cc. pipets were employed for making the subcultures from the primary subculture tubes instead of transferring 4 loopfuls, because it is more practical, being quicker and the larger inoculum

5. On the basis of the results with phenol, sodium thioglycollate medium is as satisfactory as standard extract broth for a subculturing medium even in the absence of a mercurial compound. (A word of caution is in order, however, as some lots of sodium thioglycollate medium required inoculums of about ten times the number of organisms necessary to initiate growth in standard extract broth.)

As far as could be learned, the following soaps are on the market which are claimed by the manufacturers to be germicidal:

Liquid Neko (Liquid Germicidal Soap), manufactured by Parke, Davis & Co., Detroit. Contains 0.25 per cent mercuric iodide.

Neko (Germicidal Soap, 1 per cent), manufactured by Parke, Davis & Co., Detroit. Contains 1 per cent mercuric iodide.

Neko (Germicidal Soap, 2 per cent), manufactured by Parke, Davis & Co., Detroit. Contains 2 per cent mercuric iodide.

Septicide Soap (Liquid), manufactured by National Drug Company, Philadelphia. Contains isopropyl alcohol 10 per cent, ether 10 per cent and equivalent of mercury bichloride 1:7,000.

Metaphen Soap, manufactured by Abbott Laboratories, Chicago. Contains metaphen 1:500.

Fawn Soap, manufactured by Fawn Soap Laboratory, Philadelphia. Contains chloramine-T 7 per cent.

The following toilet or household soaps were included in the tests for the purpose of determining the effect on the test organism of an ordinary soap which contains no added germicidal agent:

Fels Naphtha Soap, manufactured by the Fels Soap Company, Philadelphia.

Ivory Soap, manufactured by Proctor & Gamble, Ivorydale, Ohio.

Lifebuoy Soap, manufactured by Lever Bros., Cambridge, Mass.

Cuticura Soap, mildly medicated for toilet, manufactured by Potter Drug and Chemical Corporation, Malden, Mass.

Noxzema Brand Cream Soap, distributed by Noxzema Chemical Company, Baltimore.

Green Soap, obtained from a department of surgery.

Synol, a liquid soap manufactured by Johnson and Johnson, New Brunswick, N. J.

In table 1 are listed the results of the germicidal tests with those soaps containing mercurial compounds which require a special subculturing medium, such as sodium thioglycollate medium, for the purpose of destroying the bacteriostatic action of the mercurial compound. For the other soaps tested, standard extract broth is satisfactory. Results of the tests with soaps other than those listed in table 1 are listed in table 2.

Interpretation of Results in Table 2.—No evidence was observed of killing action against *Staphylococcus aureus* by the two brands of household soap, by four brands of toilet soap, by Green Soap or by Fawn germicidal soap in the dilutions employed. The dilutions employed in the test are comparable to the concentration of soap in lather.

In addition to taking advantage of the newer knowledge in testing mercurial disinfectants, the conditions under which the compound will have to exert its killing action in actual usage, i. e. time of exposure and concentration of the soap, should be considered. In the standard phenol coefficient test the end point is that dilution of the compound which will kill the test organism in ten minutes' exposure but not in five minutes. During the washing of hands in actual practice, the soap would not be in contact with the skin for a period of time as long as ten minutes. A minute is probably a fair estimate of the length of time a person uses soap in the careful washing of the hands (excluding surgeons). From the results listed in tables 1 and 2, only a few soaps showed killing action in the standard phenol coefficient test. These soaps were retested in shorter intervals of exposure. The results are given in table 3. In testing the germicidal action of soaps, workers have usually employed 1 or 2 per cent solutions of the soaps. A 1:50 or 1:100 dilution of soap will not lather when washing the hands. In actual washing of the hands, if a lather is produced it is a good indication that the concentration of the soap is greater than a 2 per cent solution. Walker¹⁰ stated that the concentration of soap in a good lather is about 8 per cent. In hurried washing it may be as little as 0.3 per cent, and in prolonged washing it may be as high as 20 per cent. Norton²⁰ estimated the amount of soap used in washing and found that it averaged about 0.5 per cent. The subjects washed their hands in 500 cc. of water, and Norton's figures represent the concentration of soap in the wash water and not in the lather in contact with the hands.

For the most part these findings substantiate those of Walker. The hands were washed with ordinary soap and water and dried. The clean hands were then washed with distilled water and a bar soap until a lather was produced. Sometimes the hands were washed hurriedly and only a light lather was produced. Other times the hands were washed more carefully and a heavy lather was produced. After about a half minute or a minute samples of the lather were collected in tared weighing bottles and dried over phosphorus pentoxide until constant weight. Thin shavings from the bar of soap were collected before the washing process, placed in a tared weighing bottle and subjected to drying in the desiccator along with the samples of lather to determine if there was an appreciable loss of moisture by the soap. The loss in weight was insignificant. The amount of dry residue from the lather indicated that the concentration of soap in sam-

ples of lather varied from 10 per cent weight in a light lather to 20 per cent weight in a heavy lather. In testing soaps for their germicidal action they should be tested in concentrations corresponding to that found in lather, i. e. in about 1:5 or 1:10 dilution. The results of the tests with soaps in this range of concentration are listed in table 3.

Interpretation of the Results Listed in Table 3.—Of the soaps tested, only those containing 1 or 2 per cent mercuric iodide killed *Staphylococcus aureus* in an exposure of one minute, which more nearly represents the time of exposure in ordinary washing of the hands.

Since the bacteriostatic action of mercurial compounds may be neutralized by such substances as sodium thioglycollate, the following experiment was carried out to determine if perspiration is able to neutralize the bacteriostatic action of a mercurial: Perspiration was collected, sterilized by filtering through a sintered Pyrex glass filter and dispensed into test tubes in 1.5 cc. amounts. Various dilutions of Neko bar soap containing 2 per cent mercuric iodide were prepared. The test organism, *Staphylococcus aureus*, was added in 0.5 cc. amounts to 5 cc. amounts of the

germicide. At five, ten and fifteen minute intervals a loopful of the culture-germicide mixture was transferred to a tube of perspiration, a tube of extract broth, pH 6.8, and a tube of sodium thioglycollate medium. After the culture-germicide mixture had been in contact with the perspiration for fifteen minutes, 0.5 cc. was subcultured into a tube of extract broth and 0.5 cc.

* Very difficult to work with soap in this concentration. The 1:5 dilution was prepared by heating the material in a water bath at 56 C. until solution was attained. After the dilutions were made the tubes were placed in a water bath at room temperature for a few minutes, then inoculated with the culture. The material formed a stiff gel, which made subculturing difficult.

into a tube of sodium thioglycollate medium. The results of the tests are given in table 4.

Interpretation of the Results Listed in Table 4.—Perspiration does not destroy the bacteriostatic action of mercuric iodide contained in soap.

COMMENT

In testing germicidal soaps, as with other germicides, it is necessary to employ a subculturing medium which will destroy the bacteriostatic action of the germicide which, of necessity, is transferred to the medium in the inoculum. In the case of mercurial compounds, sodium thioglycollate medium is satisfactory for this purpose. McClintock¹⁸ realized the importance of neutralizing the mercurial transferred with the inoculum, because in his publication in 1897 he stated that he subcultured from the medication tube to a tube containing ammonium sulfide to precipitate any mercury carried over in the loopful of material and then subcultured to a tube of appropriate medium, a method introduced by Geppert. It appears that this method and that described by Shippen²² are not as satisfactory as sodium thioglycollate in destroying the bacteriostatic action of mercurial compounds.

It is well to recall the meanings of the terms "disinfection" and "sterilization." The former means the act or process of destroying pathogenic germs or agents and the latter means the act or process of destroying all bacterial life. In either case the destruction is, or should be, an irreversible action. If it is possible to demonstrate that bacteria are viable after the bacteriostatic action of a compound has been neutralized, the bacteria have not been destroyed and the compound cannot be called truthfully a germicide or disinfectant. For scientific reasons the differentiation must be made between bacteriostatic and bactericidal actions.

Whether or not pathogenic bacteria, while under the influence of the bacteriostatic action of a compound such as a mercurial, are capable of producing an infection is a point which was not investigated.

By the heretofore accepted methods of testing germicides some of the germicidal soaps, especially the brands of soaps containing mercuric iodide, appeared to possess high germicidal powers. It has been observed repeatedly that the test organism *Staphylococcus aureus* appears to be killed by a 1:800 dilution of Neko soap containing 2 per cent mercuric iodide in an exposure of ten minutes. When sodium thioglycollate medium is employed as the subculturing medium the same soap in a 1:50 dilution fails to kill in an exposure of fifteen minutes. The liquid Neko soap, containing 0.25 per cent mercuric iodide, kills *Staphylococcus aureus* in an exposure of five minutes when diluted 1:5 and in a ten minute exposure when diluted 1:10 when subculturing into sodium thioglycollate medium. When subculturing into extract broth it appears that the organisms are killed in an exposure of five minutes in a dilution of 1:50 and in ten minutes by a 1:250 dilution of the soap.

Symes¹⁹ recommended McClintock's soap, containing 2 per cent mercuric iodide (Neko) as a useful means of disinfecting hands, instruments and surfaces, but after examining the results in table 1 one can see that Symes was basing his recommendations on the bacteriostatic rather than on the bactericidal action of mercuric iodide. He failed to distinguish between these two modes of action of mercurials.

Septicide liquid soap, when undiluted, killed the test organism in an exposure of five minutes, but an exposure of fifteen minutes was required to kill the test organism when the soap was diluted 1:5. The same killing power was obtained whether the subcultures were made in extract broth or in sodium thioglycollate medium, indicating that it was not the mercurial in the soap which was responsible for the killing action. Birkhaug²⁵ observed that a 1:14,000 dilution of mercury bichloride was needed to kill *Staphylococcus aureus* in ten minutes' exposure but not in five minutes when subcultures were made in extract broth. Nye²⁶ obtained

ing into sodium thioglycollate medium it was found that mercury bichloride cannot be diluted beyond 1:1,000 and still kill all *Staphylococcus aureus* organisms in ten minutes. Hoyt, Fisk and Burde²⁸ reported that less than a 1:1,000 dilution was required to kill in the same interval of time.

It is rather easy to test the germicidal action of liquid soaps in vitro. The testing of solid soaps is more difficult, because usually a dilution of the soap much more concentrated than a 1:50 dilution forms a gel too stiff for practical purposes of testing by the accepted technics. The dilution of a soap which lends itself well to manipulation with the platinum loop may not correspond to the concentration of the soap in contact with the skin during washing. The use of the agar cup method (Ruehle and Brewer²¹) as described for materials for which it is not practical to obtain aqueous solutions is not to be recommended for use with soaps, because it represents constant exposure of the test organisms to the germicide and because it does not differentiate between the bacteriostatic and bactericidal actions of the germicide. The filter paper technic, also described by the same authors,²¹ likewise does not appear to be applicable to the testing of soaps, because if a soap forms a solution sufficiently fluid to wet a piece of filter paper it is fluid enough to transfer with the standard loop.

The usual controls should not be neglected: 1. A knowledge of the resistance of the test organism to phenol is necessary. 2. It should be known that the culture medium supports growth of the test organisms when inoculated with very few of the test organisms. 3. In addition to the culture medium adequately supporting growth of the test organism, the medium should be efficient in destroying the bacteriostatic action of the germicide. 4. It is desirable to inoculate a loopful of diluted culture into tubes of the subculturing medium containing a loopful of the soaps in the highest concentration tested. The diluted culture should be prepared by adding 0.5 cc. of the test culture to 5 cc. of sterile distilled water (the same as used for preparing the dilutions of the soap) and allowing it to remain in contact for fifteen minutes or the longest time interval employed in the test. 5. It is often desirable to inoculate with a standard loopful of the diluted culture described in 4 the subculture tubes which do not show growth at the end of the incubation period. This is especially true of those tubes inoculated from the most concentrated solution of the soap. 6. When employing culture mediums containing small amounts of agar to reduce the fluidity of the medium, it is necessary to lengthen the incubation period. An incubation period of one week has been found to be adequate.

It has been recognized by many investigators that *Staphylococcus aureus* is very resistant to the action of soaps (Walker¹¹ and Colebrook and Maxted¹²). *Staphylococcus aureus* is the most important pyogenic micro-organism, so for all practical purposes it is the best test organism for testing the germicidal action of soaps.

In addition to determining the germicidal action of a soap against certain test organisms in vitro, the direct action in disinfecting the skin can be determined in a manner proposed for the evaluation of skin disinfectants, which have been summarized briefly in THE JOURNAL, Feb. 20, 1943, page 593. An in vivo method for evaluating skin disinfectants was described by

Kempf and Nungester,²⁹ in which the tail of a living animal is contaminated with living micro-organisms virulent for the animal, treating with the disinfectant, snipping off the end of the tail, inserting it into the peritoneal cavity of the animal and observing whether or not infection takes place. Another in vivo method was described by Sarber.³⁰ It differs from the foregoing method mainly in that a piece of skin from an area on the abdominal wall after being contaminated with living virulent micro-organisms and treated with the germicide is inserted into the peritoneal cavity of the same animal. For determining the action of germicidal soaps on the resident or endogenous bacterial flora of the skin the quantitative method described by Price³¹ may be employed and mathematical analysis as suggested by Bernstein³² applied.

Not only should germicidal soaps be free from irritating and toxic action on skin, mucous membranes or denuded areas, but certain actions on the skin, as suggested by Cromwell and Leffler³³ and Arnold⁸ must be borne in mind.

COMMENT BY JOSEPH V. KLAUDER, M.D.

An important practical feature in relation to these studies of the germicidal action of soap is the concentration of soap used in washing the skin. A 1 to 2 per cent solution of soap when employed for hand washing does not lather, yet a detergent action is apparent. Soap is not very soluble—a concentration much above 2 per cent at normal temperature jells and is not usually employed in ordinary hand washing. A higher concentration of soap used in hand washing is attained in the form of lather. To obtain a good lather, the act of washing with soap compound must be prolonged. The concentration of soap solution, the degree of lather and the time of exposure were pertinent factors in germicidal action of those soaps observed to exert such action.

Since soaps containing mercuric iodide exerted germicidal action, discussion of the effect of mercuric iodide on the skin is pertinent. Mercury and nickel are the two notable metals that have allergenic properties. Of the two, nickel has a higher allergenic index. The allergenic index of mercury is not high, certainly not sufficiently high to constitute an obstacle in the routine use of mercurial compounds on the skin. Ammoniated mercury ointment, for example, is frequently used. A person sensitized to mercury may be seen by the dermatologist perhaps once in a few years, among a large clientele, both clinic and practice.

To determine the primary irritant action of mercuric iodide on the skin, patch tests were performed with dilutions up to 2 per cent. Dilutions exceeding 2 per cent were not studied, since that was the maximum concentration of the chemical in the soaps studied in this report. Since mercuric iodide is not soluble in water, patch tests were performed with the chemical dissolved in 3 per cent solution of sodium thiosulfate. This percentage of sodium thiosulfate is not an irritant to the skin. It was observed that the skin of normal persons did not react to 2 per cent mercuric iodide in 3 per cent solution of sodium thiosulfate.

CRITERIA FOR RECOGNITION OF SHOCK

The common factor in the production of shock is a discrepancy between the effective circulating blood volume and the actual volume capacity of the vascular bed. The development of this fundamental change is primarily responsible for the impressive clinical symptomatology with low temperature, feeble and rapid pulse, cold skin, exhaustion and lowered arterial pressure. However, when this clinical syndrome appears, shock is often irreversible and therapy ineffective. Hence it becomes necessary to establish clinical criteria which will express the earliest, asymptomatic phase of the disparity between blood volume and vascular bed.

Many clinicians still believe that a low or falling arterial pressure constitutes an early and obligatory feature of shock. Blalock,¹ Moon,² Harkins³ and others have repeatedly pointed out that arterial pressure is a completely inadequate guide to the state of circulatory deficiency in incipient shock. Frequently the reactive vasoconstriction leads to an elevation of arterial pressure in the early stages of shock. A low blood pressure would follow later as a sign of advanced decompensation. This may account for the rare incidence of shock found by some investigators⁴ in head injuries and some other conditions when blood pressure is used as the only criterion of shock. Moreover, lowering of the arterial pressure may be maintained for several hours, without serious impairment to the circulation, as recently shown by Phemister and his co-workers.⁵ An opposite point of view regarding the value of blood pressure readings in shock has recently

been expressed by Evans and his associates,⁶ who concluded that, as compared with hemoconcentration and blood volume, the blood pressure level was the most valuable sign for early diagnosis of clinical traumatic shock in which hemoconcentration does not occur.

Hemoconcentration is probably the most frequently used single factor for recognition of shock. According to Moon it constitutes the earliest detectable manifestation of shock as well as the most accurate index of its severity. Mainly on the basis that absence of hemoconcentration expresses normal capillary permeability, this worker contends that hemorrhage should be differentiated from shock, as hemorrhage is accompanied by hemodilution and only terminally may be associated with hemoconcentration. In contrast to this concept, Blalock⁷ has shown that an irreversible typical syndrome of shock with pathologic signs of increased capillary permeability, which is as a rule associated with hemoconcentration, may be elicited by simple and slow removal of blood. Davis⁸ also observed identical pathologic features in protracted hemorrhage and in traumatic shock. Much of the experimental work being done on shock employs the withdrawal of blood as the initiating factor thus implying that the differentiation between shock and hemorrhage has not been generally accepted. Harkins summarizes this point of view, stating that a differentiation between hemorrhage and other types of shock would not have any diagnostic, prognostic or therapeutic value. In clinical cases, often both whole blood and plasma are lost. Hence hemoconcentration is not a regular feature and, except in cases of burns, cannot be relied on as an accurate sign for recognition of early clinical shock.

As the basic disturbance in all types of shock is a reduced blood volume, this estimation could be regarded as the most logical index of impending shock. The determination of blood volume was made feasible in practice by the use of Evans' blue dye. However, the reports on the use of this method in shock provide conflicting results. Although recognizing the significance of reduced blood volume, Freeman⁹ has objected to this method because the increase in capillary permeability in shock permits a considerable amount of dye to escape from the circulation. Evans and his associates found, however, that the rate of dye disappearance was the same in normal and in shocked animals. Even if this conclusion is correct, determination of blood volume would not be adequate for following the progress of

shock since this estimation could not be repeated at frequent intervals.

All other criteria, such as low venous pressure, acapnia, increased cardiac output and rise in blood potassium, are equally unreliable, inconsistent or unpractical for the early characterization of shock. A combination of the commonest manifestations and features, particularly those most suitable for practical use, constitutes a more adequate procedure in the detection and follow-up of different stages of shock. In a certain proportion of cases, peripheral collapse will progress unrecognized until a stage of irreversible circulatory deficiency has developed. The paucity of our present knowledge on this important subject indicates urgent need for further work.

VARIATIONS IN PHAGOCYTTIC FUNCTIONS

Studies of vitamin deficiencies have shown that adequate amounts of most vitamins are essential for normal resistance to infectious diseases.¹ Attempts to determine the mechanism by which resistance is lowered in the presence of vitamin deficiency, however, have been unsuccessful. Data thus far reported indicate that antibody response is practically normal in vitamin deficient animals, suggesting the probability that the observed reduction in resistance is due to reduced phagocytic functions.

Careful quantitative studies of variations in phagocytic power under different nutritional conditions have been undertaken by Cottingham and Mills² of the Laboratories of Experimental Medicine, University of Cincinnati. In their tests a standard dose of *Micrococcus candidus* was injected intraperitoneally into mice that had been maintained for several weeks on various partially deficient diets. Four hours later, smears were made of the peritoneal exudates. In a typical test control, mice were maintained at 68 F. for three weeks on a diet containing 2 mg. per kilogram of thiamine, which is adequate for this species. The four hour peritoneal smears showed that 33 per cent of the mononuclear cells had ingested the micro-organisms. This degree of phagocytosis was reduced to 20 per cent in mice previously maintained on but 1 mg. per kilogram of thiamine. Phagocytosis was not demonstrable in mice maintained for the same period of time on a diet containing as little as 0.5 mg. per kilogram of thiamine. When the thiamine intake was increased above the growth optimum (2 mg. per kilogram) mononuclear phagocytosis increased to 37 per cent. In the same animals intraperitoneal polymorphonuclear phagocytosis was reduced one half by

thiamine deficiency and increased fourfold as a result of thiamine excess (8 mg. per kilogram).

Parallel studies of phagocytosis were made in vitro with the heparinized whole blood of rats which had been maintained for several weeks on deficiency diets. In these tests blood smears were made at the end of four minutes to determine the percentage of cells showing immediate phagocytosis, and at the end of one hour to show evidence of intracellular bacterial digestion (loss of staining power, fragmentation and so on). The investigators found that rats maintained for seven weeks on a diet containing 4 mg. per kilogram of pyridoxine yielded blood whose leukocytes took up an average of 13.56 micro-organisms per cell by the end of four minutes. By the end of one hour 82 per cent of these cells showed evidence of intracellular digestion. On a partial deficiency diet (0.5 mg. per kilogram of pyridoxine), phagocytosis was reduced to 4.95 micro-organisms per cell, and intracellular digestion was demonstrable in but 15 per cent of the phagocytes. Similar or even larger reductions in phagocytic functions were noted in rats fed a diet partially deficient in thiamine, riboflavin, pantothenic acid, choline or combined vitamins A and D. Deficiencies in inositol and p-aminobenzoic acid were without deleterious effects.

Since rats and mice synthesize ascorbic acid, tests of vitamin C deficiency were made on guinea pigs. Leukocytes of adequately fed guinea pigs would take up an average of 18.3 micro-organisms per cell in vitro, and 99 per cent of these cells showed evidence of bacterial destruction by the end of one hour. On a vitamin C deficient diet, phagocytosis was reduced to 7.3 bacteria per cell, with intracellular digestion reduced to 74 per cent.

The Cincinnati investigators supplemented this study by testing the deleterious effects of quantitative variations in protein intake.³ They found that after five and one-half weeks maintenance at 68 F. rats showed a maximum phagocytic activity on diets containing 18 per cent of protein. There was a definite decrease in phagocytic activity with an increase or decrease from this level. In rats maintained at 90 + F. the phagocytic optimum diet was 36 per cent of protein. Thus adequate protein intake would seem to be fully as important as adequate vitamin intake to maintain optimal phagocytic activity (resistance to microbic infections). The immunologic optimum protein intake is higher in the tropics than in temperate climates.

This demonstration of important variations in phagocytic functions is a pioneer contribution to basic immunologic theory and may have wide clinical implications.

Current Comment

CRITICAL SHORTAGE OF QUINIDINE

For some time an acute shortage of quinidine has existed in the United States. Consumption has been high and replacement of present supplies practically negligible. As a result of its critical status, the Committee on Drugs and Medical Supplies of the National Research Council and its Subcommittee on Cardiovascular Diseases recommended that quinidine be limited to prescription use for the treatment only of heart disease. The suggested criteria for use are:

1. Ventricular tachycardia diagnosed electrocardiographically.
2. Congestive heart failure that appears definitely to have been precipitated by the sudden onset of auricular fibrillation (if not adequately controlled by digitalis).
3. Persistent premature ventricular contractions in patients who have acute coronary artery occlusion.
4. Chronic disease of the heart associated with paroxysmal auricular fibrillation, paroxysmal auricular tachycardia or auricular flutter.
5. A history of systemic embolization in a case of paroxysmal or established auricular fibrillation.

Regardless of these proposals and the publicity given to them, consumption of quinidine has continued to be high. Ordinarily, about 80,000 ounces of the drug is used during a year; present stocks amount to between 29,000 and 30,000 ounces. It is the duty of every physician to prescribe quinidine only when no other drug will elicit a favorable response, and then only in quantities not exceeding fifty tablets for each prescription. Hospital administrators can provide much assistance by insisting that the members of the staff adhere rigidly to a program which provides for the restricted use of such critical drugs as quinidine. Pharmacists have a moral responsibility to release quinidine only on prescription. This is an emergency, and whole hearted cooperation is essential.

HEALTH TRANSCRIPTION BROADCASTING IN ARIZONA

The Arizona State Medical Association, using electrical transcriptions of the series *Before the Doctor Comes*, originated by the Bureau of Health Education of the American Medical Association, has developed an excellent continuity. The broadcast is called "The Medical Quarter Hour." The transcription itself occupies only ten minutes, so the program is opened with a familiar theme, for which a popular waltz record is used. Then follows an announcement to the effect that the stations of the Arizona network "present at this time a transcribed public service broadcast made available through the sponsorship of the Arizona Medical Association." Introductory remarks are made by the announcer, who describes the purpose of the broadcasts and gives forecasts of the programs to come. The transcription is then introduced and played. After the transcription, a message is read from the Arizona Medical Association which invites the listeners to send in comments and suggestions and offers to answer questions suggested by the broadcast. If time permits, a Health Hint appropriate to the program is added. For example, in connection with the transcription

dealing with "Sniffles" there are some suggestions pertinent to colds and other related conditions. This combination of music, local material and a transcribed message from the American Medical Association is the kind of use for which the transcriptions were originally prepared. This way of giving radio listeners health information from the American Medical Association through community and state societies automatically makes clear the relationship between the family doctor and the medical organization to which he delegates many of his important functions, including health education. The Arizona broadcasts are described here with the thought that this method may contain suggestions for similar use of the available transcriptions in other localities.

THE TRINIDAD OUTBREAK OF EQUINE ENCEPHALOMYELITIS

Equine encephalomyelitis in Venezuela and Colombia is a mosquito transmitted infection caused by a virus that is related to equine neurotropic viruses in this country but immunologically distinct. In October 1943 an explosive outbreak of encephalomyelitis attacked horses, mules and donkeys in the island of Trinidad, 6 miles off the Venezuelan coast at the nearest points. According to Gilyard,¹ who investigated the Trinidad outbreak, there is good reason to conclude that it was due to mosquitoes flying across from the mainland. The prime vector of the epizootic may have been the mosquito *Mansonia titillans*, but other species cannot be definitely excluded. The virus was obtained from *M. titillans* in the field on guinea pig inoculations, and Venezuelan vaccine gave complete protection. In addition to the account of the mosquito conveyance of the disease, Gilyard reports also a human case of Venezuelan encephalitis. About six weeks before the equine outbreak a seaman of the U. S. Navy died of encephalitis on the gulf coast of Trinidad about 20 miles north of the subsequent animal outbreak. Just how this seaman was infected is not known, but the diagnosis of equine encephalitis was confirmed by appropriate tests of the brain. This appears to be the first human case in which death has been traced to equine encephalitis of the Venezuelan type. It seems to be established that the three strains of equine encephalitis now known to exist in the Western Hemisphere can cause fatal infections in man.

THE DISTINGUISHED SERVICE MEDAL

The Distinguished Service Medal of the American Medical Association will be presented for the seventh time at the Opening General Meeting on Tuesday night, June 13, in the ballroom of the Palmer House, Chicago, during the annual session of the American Medical Association in Chicago, June 12-16, 1944. The medal was awarded, for the first time, in 1938 to Dr. Rudolph Matas of New Orleans, in 1939 to Dr. James B. Herrick of Chicago, in 1940 to Dr. Chevalier Jackson of Philadelphia, in 1941 to Dr. James Ewing of New

1. Gilyard, R. T.: Mosquito Transmission of Venezuelan Virus Equine Encephalomyelitis in Trinidad, Bull. U. S. Army Med. Depart. 75:96 (April) 1944.

York, in 1942 to Dr. Ludvig Hektoen of Chicago and last year to Dr. Elliott P. Joslin of Boston. This award is recognized as one of the most distinguished honors within the gift of the American Medical Association. Any Fellow of the Association may submit nominations, which should be sent, together with a record of the scientific services of the nominees, to the chairman of the Committee on Distinguished Service Award, Dr. A. A. Walker, 2250 Highland Avenue, Birmingham, Ala., or to the Secretary of the Association at 535 North Dearborn Street, Chicago. Of all nominations received by the committee, five are submitted to the Board of Trustees of the Association, from which the Board selects three to be submitted to the House of Delegates at its first meeting at the time of the annual session. Immediately on submission of the nominations by the Board of Trustees, the House of Delegates by official vote selects the recipient of the honor, to whom the Distinguished Service Medal is presented at the meeting at which the President-Elect is installed as President, which is usually on Tuesday evening of the week of an annual session. An extended list of distinguished physicians nominated for this award will enable the committee, the Board of Trustees and the House of Delegates, all of whom participate in the selection, to determine for 1944 a recipient of distinction, whose nomination will reflect favorably on himself and the Association.

TRANSPORTATION TO THE ANNUAL SESSION

According to current rules of the Office of Defense Transportation, reservations for pullman space of the railroads cannot be made more than thirty days in advance. The time of the annual session is June 12 to 16. Many physicians will be coming to Chicago for various smaller meetings that occur on June 10 and 11; others will be planning to return home at various times during the meeting. Therefore this comment is published to warn physicians well in advance of the necessity for making reservations for transportation at the earliest possible moment in relation to the trip. The entire trip should be planned so that reservations may be secured for coming to Chicago and returning home. This may require two trips to the reservations office—one for the trip going and the other for the trip returning. Transportation out of Chicago is under great pressure even in ordinary times. It will not be wise for a doctor to wait to purchase his return transportation until after his arrival in Chicago.

"THE STORY OF DR. WASSELL"

Next week the city of Little Rock, Ark., will be the site of a première of an unusual picture called "The Story of Dr. Wassell," directed by Cecil B. DeMille and produced by Paramount. The picture portrays the career of Dr. Corydon M. Wassell of Little Rock, somewhat romanticized, but follows nevertheless the high points of his life. Thus it includes his practice in Arkansas, his service as a medical missionary with a feeling for research, and his great accomplishment in

transporting a group of wounded sailors across Java while the Japs were invading the island. Probably the most dramatic single incident in the picture is the introduction of the voice of the President of the United States when in his fireside chat on April 28, 1942 he quoted the official Navy report regarding Dr. Wassell and described the accomplishment for which he received the Navy Cross and the Officer's Cross in the Order of Orange Nausau from Queen Wilhelmina of Holland. This picture should be an inspiration to every physician who, in the midst of his busy life these days, gets an opportunity to see it. It should, of course, do much to carry to the American people the great service that American physicians are rendering in the war.

BORIC ACID CAUSES MORE INFANT DEATHS

Boric acid accidentally administered in milk formulas given to infants has caused the deaths of 4 infants and affected 20 others, some of whom may also die, according to recent press reports. This occurred in a New London, Conn., hospital. Boric acid crystals, according to the reports, were incorporated in the milk formulas by mistake because of their similarity in physical appearance to dextrose crystals. Unfortunately this is not the first time that boric acid has been responsible for accidental infant deaths in a hospital. In 1927, through a confusion of technic, infants in the nursery of a Chicago hospital were given boric acid solution instead of drinking water, and 6 of them died. Although these accidents and a few others like them have occurred only rarely and have been widely separated geographically and by time, the need for more careful protective devices is apparent. Boric acid, although it has only minor toxic properties as compared with other substances, is extensively used in the care of the skin and eyes of infants, so that it must be strictly segregated from those substances which may be incorporated into infant foods.

AID TO DIAGNOSIS OF MENINGO- COCCIC INFECTIONS

The early accurate diagnosis of meningococcic infections has assumed more than ordinary importance in view of the congestion of populations in industrial and military areas. Recently, Bernhard and Jordan¹ found meningococci in smears from purpuric lesions in 27 of 40 cases of meningococcic infections with such lesions. On culture the organisms were isolated in 35 of these 40 cases. In 25 cases of meningitis which showed clear spinal fluid with normal chemical constituents, positive spinal fluid cultures were obtained. The authors conclude from this high proportion of positive results of smears and cultures from the purpuric lesions that this method is a highly satisfactory procedure for the rapid and early diagnosis of meningococcic infections. This may prove a particularly valuable aid to diagnosis in certain types of clinical cases, especially those without early manifest signs of meningeal involvement.

MEDICINE AND THE WAR

In this section of The Journal each week will appear official notices by the Committee on War Participation of the American Medical Association, announcements by the Surgeons General of the Army, Navy and Public Health Service, and other governmental agencies dealing with medicine and the war, and such other information and announcements as will be useful to the medical profession.

NUTRITIONAL ASPECTS OF CONVALESCENT CARE

It may be assumed that the soldier or sailor who has subsisted on normal service rations is in an excellent nutritional state up to the time he becomes disabled by illness or disease. Exceptions must be made of men who, because they were isolated when they incurred their disability, had not received full rations.

As soon as injury or disease occurs, malnutrition almost always begins. This is the result of two processes: first "toxic destruction of protein"—i. e., the direct effect of disease or injury in promoting destruction of tissues—and, second, diminished intake of food, because of inability or disinclination to eat. Both of these processes bear some relation to the severity of the injury or disease.

Although some wastage of tissue can be tolerated and has no easily demonstrable effect on strength and efficiency, the extent of such "harmless" deficiency is ill defined. There is ample evidence that any considerable nutritional deficiency is distinctly harmful: It first reduces tolerance for exceptional exertion; in its most severe form it is altogether incapacitating. Even a mild degree of malnutrition should, therefore, be prevented because, though its evil effect may be undetectable, it marks a step toward incapacity and each step makes physical efficiency more precarious.

The "toxic destruction of protein" can be alleviated only by effective treatment of the disease or injury from which it originates. Its evil effects are, however, exaggerated by inadequate dietary intake. Wasting from this cause can be prevented in a large proportion of patients, and even "toxic destruction of protein" may be reduced by the effective administration of fluid and food in proper quantities and proportions. In addition, by improving the general state of health these measures promote and shorten the processes of repair.

Attention is likely to be given to the dietary needs of persons who are suffering from serious diseases and injuries, although the regimen may not always be wisely directed. From a military standpoint more man-days could be gained by accelerating the recovery of those with less grave conditions who may be rapidly returned to active service. Every effort should be made, therefore, to prevent malnutrition and minimize wasting in acute or minor casualties as well as in men with more serious disabilities.

The average medical officer is so preoccupied with the specific treatment of the disease or injury which confronts him that he is prone to overlook details of dietary management, especially when there are no urgent indications. In

addition, even if he has the best will in the world, he may be insufficiently acquainted with fundamental principles of nutrition. For both these reasons it would be well in hospitals with a sufficiently large staff to place the responsibility for general supervision of dietary management and nutrition of patients on a particular member or members of the medical staff of the hospital. These nutritional medical officers should not order diets for all the patients in the hospitals, but they should rather act as instructors and consultants to the medical officers in charge of wards and should see that good dietary principles are observed throughout the hospital.

Outlined in succeeding paragraphs are the general principles underlying nutrition, knowledge of which may be expected to enable the medical officer to mitigate wasting and to accelerate recovery of patients.

Emphasis should be placed on the importance of prevention rather than correction of nutritional deficits. The proverb "An ounce of prevention is worth a pound of cure" is nowhere more applicable than in the field of nutrition. By focusing his attention on the diets at the very onset of illness, the medical officer can avoid the necessity of treating the serious effects of prolonged malnutrition.

GENERAL PRINCIPLES

Obvious but often overlooked is the fact that food offered to a patient is of no value unless it is eaten. The amount of food actually consumed should be ascertained. If food offered to the patient is not eaten, the reasons must be learned and, if possible, corrected. Anorexia must be regarded as a challenge, not as an inevitable and irremediable consequence of disability. Although patients should be encouraged to eat as varied a diet as possible, idiosyncrasies cannot be altogether neglected. Failure to eat may arise from physical weakness, exhaustion or the fact that the necessary motions are painful. It may be necessary to feed patients under these conditions. Fluid or semisolid diets may be essential for seriously ill patients. In the absence of gastrointestinal disturbances patients who will drink freely can usually be given adequate protein and calories in the form of fluids if advantage is taken of the sense of thirst. This sense should not be too much dulled by water and nonnutrient fluids; nutrient fluids should be made available to quench it. Thirst may be stimulated by the intelligent use of salt (see next section). But fluid or semisolid diets, because they are not conducive to appetite, should not be continued if the patient is able to take solid food. The chief reason for giving fluids, semisolids and soft foods to the sick is to relieve them of the work of cutting or masticating the foods. All foods become liquid in the gastrointestinal tract except milk, which first coagulates in the stomach. In some conditions frequent feedings are desirable; in this case the total diet is best divided equally into the required number of meals. Intermediate feedings (between meals of a regular dietary) may only spoil the appetite for the regular meals. Night feedings, shortly before sleep, are usually well tolerated; high calory feedings, instead of the usual light fluids, may be given to advantage at this time.

After a conference on Nov. 16, 1943, the Committee on Convalescence and Rehabilitation requested Dr. J. P. Peters, Yale University, and Dr. Robert Elman, Washington University, to draw up a report embodying methods of treatment which will maintain the best possible nutritional state in patients who are sick or injured. This request was made because of the belief that the use of well established principles of nutrition may diminish the catabolic effects of illness and therefore shorten the duration of convalescence. This report was presented at a meeting on Dec. 17, 1943 and was then modified by the authors and the committee to its present form. Acknowledgment is made of the contribution of the following men to the discussions which led to this report: Drs. Fuller Albright, R. C. Darling and Allan Butler, Harvard University; Co Tui, New York University; L. E. Holt Jr. and J. E. Howard, Johns Hopkins; Ancel Keys, Minnesota; R. F. Loeb, Columbia; S. C. Madden, Rochester; W. C. Stadie, Pennsylvania.

It is also obvious that whenever possible the patient should eat his necessary food in the normal way. It is not only unnatural but laborious for the doctor and distressing to the patient to meet all dietary requirements by means of other devices. Tube feedings or parenteral injections should not be employed merely as a means of evading the difficulties which arise from simple anorexia. On the other hand, these two methods are preferable to malnutrition and should be used when indicated. Their use, indeed, should make it possible to avoid malnutrition even if the patient is unable to take any food or fluid by mouth.

DIETARY ESSENTIALS

Water.—Enough water must be given to provide for insensible and sensible perspiration and for the production of sufficient urine to enable the patient to excrete the waste products that must be eliminated, without depleting the essential water stores of the body. Loss of water by the skin varies with the environmental temperature and the total caloric expenditure. The best criteria of an adequate water supply are:

(a) The volume of urine, which should not fall below 1,000 cc. in febrile patients; (b) the specific gravity of the twenty-four hour urine, which should not exceed 1.020, and (c) normal elasticity of the skin and subcutaneous tissues, the moist appearance of the tongue and the absence of uncomfortable subjective sensations of thirst.

Forcing fluids—i. e., inducing a patient to take uncomfortably large quantities of plain water—is seldom indicated. It is tiring and distressing to the patient and often impairs appetite. If a large intake is necessary, enough salt should be given to promote thirst.

Salt.—Animals derive their sodium salts almost entirely from sodium chloride added to their food. If the sodium salts of the body become depleted, water is not properly retained and dehydration results. In addition, sodium deficiency promotes circulatory failure. Patients with sodium depletion lose thirst, appetite and strength. If the sodium deficit becomes great, circulatory collapse may supervene.

Normal kidneys conserve sodium and chloride most efficiently. Chloride practically disappears from the urine as soon as its concentration in the serum falls appreciably below normal. If the urine contains little or no chloride (that is, yields little precipitate when treated with silver nitrate), it may be presumed that there is a salt deficiency. An exception must be made of patients with gross renal insufficiency, lobar pneumonia, advanced chronic tuberculosis and other destructive pulmonary diseases. In these conditions the kidneys do not retain their normal capacity to conserve salt. Consequently, urinary chloride excretion may continue after serum chloride has fallen below normal limits.

The insensible perspiration (fluid lost through the lungs and by the skin without sweating) amounts to 1,000 to 1,500 cc. and contains no salt. Sweat and exudates do contain salt that must be replaced. The stomach has no regard for the salt which does not cease even when serum sodium and chloride are depleted. Administration of water (ice in water) by mouth in the face of persistent vomiting only washes salt from the body and enhances dehydration, as does continuous gastric suction and lavage. For lavages of all kinds, isotonic solution of sodium chloride, not water, should be used.

All persons, unless they have congestive heart failure or nephritis with edema, should receive at least 5 Gm. of sodium chloride daily. The average normal diet contains more than this. If, however, patients do not eat enough of their diets or subsist chiefly or entirely on simple fluids, containing only carbohydrate, extra salt should be given. This may be introduced in broth or tomato juice or even in milk and fruit juices. Administration of adequate amounts of salt will often increase the intake of both food and fluid by creating appetite and thirst. Salt-depleted patients will not eat or drink well.

Protein.—Protein is indispensable; it cannot be replaced by any other food. A normal subject, starving, loses about 1 Gm. of tissue protein per kilogram of body weight per day. This deficit can be reduced to 0.3 to 0.5 Gm. by the administration of high calories in the form of carbohydrate and fat; it cannot be prevented entirely. Moderate amounts of carbohydrate alone will reduce protein loss considerably. In acute febrile diseases and after serious injuries protein wastage may rise to 3 or more grams per kilograms of body weight per day. This can be reduced only slightly by feeding carbohydrate. There is evidence that the lost tissue protein can be partly or wholly replaced and consequently that wasting can be mitigated or prevented by the administration of large amounts of protein and sufficient amounts of carbohydrate and fat to provide for the caloric requirements of the patient. This is a matter of great importance, since loss of tissue protein sacrifices the substance of liver and other important organs. It also results in depletion of serum proteins (hypoproteinemia), which ultimately leads to nutritional edema.

Every effort should be made to prevent this loss by administration of diets containing adequate amounts of protein of high biologic value containing all the essential amino acids in proper proportion. For this purpose, milk and eggs (the latter preferably cooked) may be used if patients are unable to take solids. Ground meats may, however, be given earlier and more freely than is generally believed.

Diets for sick or injured persons should contain 100 Gm. or more of protein daily. Nothing less than 1 Gm. of protein per kilogram of body weight per day can be regarded as a safe subsistence ration for a normal adult.

Carbohydrate.—A small amount of carbohydrate, perhaps 100 Gm. per day, is required to prevent ketosis in man. If this is not given, protein is broken down to provide carbohydrate. Granted sufficient protein and this minimum of carbohydrate, well nourished subjects can derive most of the additional calories needed from body fat, without serious injury.

Fat.—The least important element of the diet in acute disease is fat. Indeed, fat comprises the only large store of calories on which the body may draw without depleting essential tissues. In prolonged wasting conditions, however, fat deposits may become exhausted. It is, therefore, advisable if possible to prevent excessive loss of fat by giving high calories. For this purpose fat itself is peculiarly suited because it provides the greatest number of calories in the smallest bulk. The digestive system of most ill or injured persons tolerates, digests and absorbs fat well if it is given in palatable form with suitable carbohydrate vehicles. Nevertheless, if there is a limitation of the amount of food a patient can take, it is far better to give precedence to protein.

Vitamins.—Starving animals appear to acquire at first no vitamin deficiencies because for short periods they derive adequate vitamins in suitable proportions from their tissues. However, vitamin deficiencies develop after considerable periods on inadequate diets. The utilization or excretion of certain vitamins may be specifically increased by particular diseases, especially those which accelerate metabolism. Nothing is as effective in preventing vitamin deficiencies as a generous mixed diet. Complete oral mixtures of vitamins, especially brewers' yeast and other satisfactory preparations of vitamin B elements, when given in adequate quantities may destroy the appetite for food. They should therefore be used with caution as supplements to diets. Although complete vitamin mixtures for parenteral injection are not available, some important vitamins may be given readily.

Although a full well balanced diet best meets nutritional needs, it is frequently impossible for the injured or sick to take such a diet. It then becomes necessary to give priority to the food elements which are most urgently needed. The accompanying table lists in order of importance the various dietary constituents and the amounts of each which are required.

In patients previously well nourished, suffering from a disability or illness of short duration no serious harm develops from failure to maintain a high calory or fat intake, since the necessary calories will be derived from body fat if the minimum requirements for water, salt, protein and carbohydrate are met. When the patient is undernourished and the illness is long drawn out, fat stores may be depleted. The maintenance of adequate caloric intake then changes from a merely desirable part of therapy to a matter of more urgent importance.

If a patient had ample stores of vitamins before becoming sick, special efforts to supply these essential elements are not necessary during most acute illnesses. If the patient had been previously depleted of vitamins or is unable for a long period to take a balanced diet, vitamins should be administered.

TUBE FEEDING

Feeding by stomach tube is not a satisfactory procedure. Insertion of the tube is time consuming for the physician and often not pleasant for the patient. In unconscious patients the possibility of aspiration of injected material into the lungs introduces an element of danger.

In general, tube feeding should not be used until an honest effort has been made to have the patient eat. Such effort includes provision of palatable food of a type most appealing to the patient and some personal attention by the physician to overcoming the patient's distaste for food. When gavage is used, it should always be done as a temporary expedient with the patient's full knowledge that it will be discontinued as soon as he eats an adequate amount. However, there are

Dietary Constituents and Amounts Required

	Minimum Need	Average Requirements in Sick Patient
1. Water	2,000 cc.	3,000 cc.
2. Salt	5 Gm.	10 Gm.
3. Protein	75 Gm.	100-150 Gm.
4. Carbohydrate	100 Gm.	100-300 Gm.
5. Fat	(See discussion)	(See discussion)
6. Vitamins	(See discussion)	(See discussion)
7. Calories	(See discussion)	(See discussion)

clinical situations in which tube feeding is the only practicable means of preventing serious malnutrition of the patient. It may be necessary to resort to this procedure when the amount of nursing and other ward assistance is limited so that personnel is not available to spoon feed patients who are unable to feed themselves. In most instances the nasal route should be used for insertion of a moderate-sized tube, and the tube should be allowed to remain in place, with regular feedings administered at two to four hour intervals.

The material inserted through a feeding tube should always be warmed to body temperature. Large volumes and rapid rates of injection should be avoided. The material should be concentrated and should contain the necessary amounts of salt and protein, as well as carbohydrate and fat, for the provision of caloric needs, as for any well balanced diet. Casein hydrolysates in powdered form can be used to provide an adequate nitrogen intake, especially when there is evidence (diarrhea) that whole protein is inadequately digested. Hydrolyzed protein can often be assimilated by sick patients in much larger amounts than whole protein.

PARENTERAL FEEDING

Parenteral injections are to be looked on as temporary substitutes for normal eating, should never be used in the absence of specific indications and should never be regarded with complacency. However, all physicians are familiar with the great benefits which have accrued from the availability of methods for the parenteral administration of water and salt to patients unable to take these essential substances by mouth. Under many circumstances the provision of other nutrient materials parenterally has as great importance for the welfare of the patient as does the parenteral administration of fluid.

Parenteral feedings should be planned always with the view of introducing, in the smallest practicable volume of fluid and in the shortest time, the quantities and proportions of materials required to meet the needs of the recipient as they have been outlined. Administration of excessive amounts of fluid over unnecessarily long periods distresses and exhausts patients and wastes material and the time of attendants.

Water.—Water is the vehicle for all parenteral nutrient materials. At times, however, it may be necessary to give some water in addition to the amounts required for solvent purposes. In this case, since pure water cannot be injected, dextrose solution must be used. The dextrose is burned, providing calories, while the water is left in the body. The proportions of sugar and water may be varied in accordance with the needs for these two constituents.

Enough water should be given to replace water lost by insensible and sensible perspiration, vomiting, diarrhea and exudation and, in addition, sufficient to provide 1,000 cc. of urine (1,500 cc. if there is high fever and reason to suspect excessive toxic destruction of protein). It is impossible to state with accuracy the exact amount needed because of the wide variation under different clinical conditions. However, when a patient is unable to take any fluid by mouth, his minimum requirements will rarely be less than 2,000 cc. per day and will usually be 3,000 cc. or more.

Salt.—The salt requirements of an individual can be adequately supplied over moderate periods by the injection of an adequate volume of isotonic solution of sodium chloride. The ratio of chloride to sodium is higher in such solutions than it is in body fluids, but, if enough is given to produce an adequate volume of urine, the kidneys will excrete the excess chloride, while retaining sodium to form the necessary bicarbonate. Sufficient potassium, magnesium, calcium and phosphate will be obtained from destruction of tissues.

A minimum of 5 Gm. of sodium chloride a day should be given to all patients. Febrile subjects or persons who sweat excessively should receive additional amounts. In case of vomiting, enough should be given to replace salt lost in the vomitus. For subjects receiving water by mouth vomitus may be estimated to contain the equivalent of about 5 Gm. of sodium chloride per liter. For subjects receiving no water by mouth, fluid lost by vomiting should be replaced by an equal volume of saline solution. If the patient has become dehydrated by vomiting before treatment is instituted, enough saline should be given at the onset of therapy to repair the deficit; this may require as much as 5 to 10 liters of salt solution.

In addition to the saline solution, sufficient water should always be given in the form of dextrose solution to provide for the insensible perspiration, which contains no salt. This amounts usually to from 1,000 to 1,500 cc. daily, depending on the size and metabolism of the subject.

Dextrose.—A certain amount of carbohydrate is required to prevent ketosis and to mitigate nitrogen loss. Dextrose solution also permits the administration of approximate amounts of water without salt. As little as 100 Gm. of dextrose a day will prevent the gross ketonuria of starvation (i. e., excretion of enough ketones to yield positive nitroprusside tests in the urine) but will not prevent rise of ketone bodies in the blood. It is better to give dextrose in two doses than one, in order to insure continuous utilization. To provide enough calories to minimize protein wastage more than 100 Gm. daily is required.

Only 5 per cent dextrose solution should be used subcutaneously. Concentrations from 5 to 50 per cent may be injected intravenously. It is generally held that solutions stronger than 10 per cent should be used only in small quantities in conditions of emergency, because such solutions are likely to cause venous thrombosis. Concentrations as great as 15 per cent may, however, be used if they are introduced slowly enough and if there is a free flow of blood around

the needle in the vein into which they are injected. A free flow of blood and slow introduction of fluid dilutes the solution at the point of injection to an innocuous concentration.

Dextrose can be added to solutions of salt and to protein hydrolysate without consideration of its osmotic contribution, provided it is injected so slowly that the dextrose is utilized as rapidly as it enters the body.

Protein.—Protein may be given as transfusions of whole blood, plasma, hydrolyzed protein or mixtures of amino acids.

Transfusions of whole blood and infusion of normal or concentrated plasma are not ordinarily thought of as nutritional measures. They are used for maintaining blood volume and circulation. Every hundred cubic centimeters of normal blood contains about 15 Gm. of hemoglobin and 4 Gm. of plasma protein. Hemoglobin is not suitable for replacement of tissue protein. However, injected plasma protein is metabolized to some extent, and so provides a source of nitrogen nourishment and protects, in part at least, against tissue wastage.

Solutions of hydrolysates of casein or other high grade proteins have recently been employed and represent a more physiologic method of providing nitrogenous food parenterally, because food protein is normally hydrolyzed before absorption. Of the various hydrolysates available only one has been demonstrated to be safe, well utilized and capable of maintaining nitrogen equilibrium in man. This hydrolysate is prepared from casein by digestion with pancreatic enzymes.¹ Acid hydrolysates should have certain theoretical advantages. Up to the present time it has been impossible to produce acid hydrolysates without destroying certain essential amino acids, notably tryptophan. Since means of circumventing this oxidation have been devised, satisfactory acid hydrolysates may become available. Mixtures of pure amino acids suitable for injection have definite advantages, but they are expensive and are not yet available in large quantity.

It has been demonstrated that the nitrogen requirements of animals and patients may be supplied for long periods by infusions of casein hydrolysate or pure amino acid mixtures. Like all other parenteral methods of feeding, however, this must be regarded as a temporary substitute for normal eating. It is a procedure, moreover, that requires careful attention to detail.

The casein hydrolysate is usually prepared in 5 per cent concentration dissolved in 5 per cent dextrose solution. When neutralized to a pH of 6.5, a liter of this solution contains 5 Gm. of sodium chloride. A liter of such a solution contains the equivalent of 50 Gm. of protein. Between 1.5 and 2 liters per day are therefore required to meet the basic demands of a normal man for protein. If solutions of casein hydrolysate are properly prepared, they should provoke no pyrogenic reactions. If they are injected too rapidly (faster than 500 cc. of a 5 per cent solution per hour in an adult of normal size) nausea or vomiting may be induced.

Fat.—At present no preparation of fat suitable for intravenous injection is available. Such preparations are feasible and have been made and used in emulsions up to 30 Gm. of fat per hundred cubic centimeters. The fat emulsions would have great theoretical value in any situation in which maintenance of a high caloric intake by parenteral injection is indicated, since each hundred cubic centimeters of a 30 per cent fat emulsion would provide 270 calories.

Vitamins.—During short sicknesses vitamins are not required, especially if the patients are not extremely malnourished. However, there are available preparations of certain vitamins for parenteral use, which should be given to patients who cannot eat a balanced diet during the course of prolonged disability. The most important ones are listed, with the daily doses recommended: thiamine (B_1), 10 mg.; riboflavin (B_2), 5 mg.; nicotinic acid, 20 mg.; ascorbic acid (vitamin C), 100 mg.

1. In this report all mention of casein hydrolysate for intravenous use refers to this enzymatic hydrolysate, the product of a single manufacturer. It is probable that other preparations will be developed in the future and proved by adequate clinical trial to be equally safe and efficacious.

GENERAL DIRECTIONS FOR PARENTERAL FEEDING

It is best to plan in advance the quantities of water and other constituents that will be required for the day, the times at which they are to be given and the routes by which they are to be administered. The total amounts of each component should first be estimated, after which they are translated into terms of parenteral materials that are available. Efforts should be made to use no more water than the patient requires.

Only isotonic solutions should be given subcutaneously, that is, normal saline or 5 per cent dextrose. The intravenous route is to be preferred to the subcutaneous for dextrose solutions, since dextrose tends to abstract water from the tissues at first because it diffuses more slowly than salt does. Saline solutions should not be reinforced with dextrose for subcutaneous injection because this makes a hypertonic solution. Dextrose can be added as desired to intravenous solutions because it is consumed, leaving only water. The temporary osmotic effect it produces is negligible or may be advantageous. If it is impossible to prepare the solutions fresh according to prescription, the desired concentration of dextrose may be made up by the addition of the required amount of sterile 50 per cent dextrose from ampules.

Solutions no stronger than 10 per cent of dextrose can be administered at the rate of 9 cc., or about 150 drops, per minute. If 15 per cent dextrose solution is used, the rate should be reduced to 6 cc., or about 100 drops, per minute. As a further precaution against venous thrombosis, the smallest possible needle (22 to 26) with a short bevel should be used, and care should be taken that it is held in place in such a way that the blood flow in the vein around the needle is not obstructed.

Casein hydrolysate solutions can be made up in 10 per cent concentration, which can be diluted to 5 per cent with dextrose solutions. Solutions prepared from the powder have a pH of about 5.0. They should be brought to a pH of 6.5 by the addition of sodium hydroxide before use.

EXAMPLES

1. It is desired to provide a nonfebrile patient who is unable to eat or drink but is not vomiting nor sweating and who has no large, exposed exuding surface for one day with water, salt and enough dextrose to prevent gross ketosis:

Water	1,500 to 2,000 cc.
Salt	5 to 8 Gm.
Dextrose	100 Gm.

1,000 to 1,200 cc. of 10 per cent dextrose and 500 to 800 cc. of isotonic solution of sodium chloride will meet these requirements closely enough. The total amount selected should preferably be given in two equal instalments.

2. If there has been a large antecedent deficit of salt as a result of vomiting, sweating or transudation, the proportions of salt may be increased.

For example:

Water	3,000 cc.
Salt	27 Gm.
Dextrose	100 Gm.

In this case 100 Gm. of glucose or 200 cc. of 50 per cent dextrose is added to 3 liters of isotonic solution of sodium chloride and divided into two portions in the same manner.

3. To meet the requirements for the nutrition of a patient who will be unable to take any food or fluids for some days and therefore should receive a nutrient which will provide an adequate amount of some protein substitute:

Water	3,000 cc.
Casein hydrolysate	100 Gm.
Dextrose	300 Gm.
Salt	10 Gm.

This will require 2 liters of 5 per cent casein hydrolysate, 5 per cent dextrose solution and 1 liter of 10 per cent dextrose solution, a total of 3,000 cc. Since the casein hydrolysate is neutralized, it will contain 5 Gm. of salt per liter, or 10 Gm. in 2 liters. Other convenient formulas can be devised by which the volume can be kept below 3,000 cc. The selected amount of solution should be injected over a period of about four hours or, preferably, in two equal instalments of two hours each. If the patient is given transfusions of whole blood or plasma, the amount of casein hydrolysate will be decreased.

MISCELLANEOUS

WARTIME GRADUATE MEDICAL MEETINGS

Additional subjects and speakers for Wartime Graduate Medical Meetings have just been announced:

At Station Hospital, Dow Field, Bangor, Maine: Acute Abdominal Emergencies, Dr. Edward H. Risley, May 16.

At Dispensary, U. S. Naval Air Station, Brunswick, Maine: The Pneumonias and Other Respiratory Infections, Dr. Alexander M. Burgess, May 18.

At Station Hospital, Fort Banks, Boston: Blood Dyscrasias and Transfusions, Dr. William B. Castle, May 18.

At Dispensary, U. S. Naval Construction Training Center, Davisville, R. I.: Cardiac Neuroses, Cardiac Emergencies and Cardiac Rehabilitation, Drs. Samuel A. Levine and T. Duckett Jones, May 18.

At Fort H. G. Wright, Fishers Island, New York: Stomach, Biliary Tract and Intestinal Disorders, Dr. John C. Leonard, May 18.

At Station Hospital, Bradley Field, Windsor Locks, Conn.: Acute Abdominal Emergencies, Dr. Thacher W. Worthen, May 18.

At Camp Kilmer, New Jersey: Rickettsia Infections, Dr. William Sawitz, May 8; Water and Solute Balance in Health and Disease, Dr. John Eiman, May 29.

At England General Hospital, Atlantic City, N. J.: Malaria, Dr. W. Harding Kneedler and Dr. William Sawitz, May 2; Leishmaniasis, Dr. Julia Morgan and Dr. William Sawitz, May 16.

At Fort Monmouth, New Jersey: Diagnosis and Treatment of the Neuropsychiatric Patient in a Naval Hospital, Comdr. T. N. Spessard, May 3; Head Injuries: Their Diagnosis and Treatment, Dr. Temple Fay, May 10; Relationship of Pain and Tenderness to Body Mechanics, Dr. John C. Howell, May 17; Treatment of Burns and the Closure of Surface Defects by Skin Grafts and Flaps, Dr. Hans May, May 24; Viral Pneumonia, Dr. Hobart Reimann, May 31.

At Indiantown Gap, Pa.: Head Injuries: Their Diagnosis and Treatment, Dr. Temple Fay, May 3; Acute Glomerulonephritis (Trench Nephritis), Dr. George Morris Piersol, May 10; Blood and Plasma Bank and the Use of Its By-Products, Lieut. Clifford K. Murray, May 17; Malignancy as Seen in the Armed Forces, Dr. Stanley Reimann, May 24; Limitations of Fluoroscopy, Dr. W. Edward Chamberlain, May 31.

At Philadelphia Naval Hospital: Management of Pneumonia, Dr. Harrison F. Flippin, May 12; Limitations of Fluoroscopy, Dr. W. Edward Chamberlain, May 26.

At the U. S. Naval Hospital and U. S. Naval Academy Dispensary, Annapolis, Md.: The Pneumonias and Other Respiratory Infections, Dr. Luther L. Terry, May 19.

At Camp Lee, Virginia: Rheumatism, Lieut. Joseph L. Hollander, May 5; Prevention and Treatment of Wound Infections with Sulfonamides, Lieut. Col. Okla W. Sicks, May 12; Traumatic Surgery of the Abdomen, Dr. Frank S. Johns, May 19; Modern Diagnosis and Treatment of Pulmonary Tuberculosis, Dr. A. Barklie Coulter, May 26.

At Langley Field, Virginia: Anesthesia—Selection and Contraindications, Capt. Allen Widome, May 2; Psychosomatic Medicine, Lieut. Sidney U. Wenger, May 9; Traumatic Arthritis, Lieut. Comdr. Judson D. Wilson, May 16; Rheumatism, Major Terence Lloyd Tyson, May 23; Traumatic Surgery of the Abdomen, Dr. Robert L. Payne, May 30.

At Newton D. Baker General Hospital, Martinsburg, W. Va.: Crushing Injuries of the Extremities, Dr. Floyd Shaffer, May 1; Physiotherapy in War Wounded, Lieut. Comdr. Harry Etter, May 8; Psychosomatic Medicine, Dr. Jacob H. Conn, May 15; Shock, Dr. C. Martin Rhode, May 22; Prevention and Treatment of Wound Infections with Sulfonamides, Dr. Warfield M. Firor, May 29.

At Fort Eustis, Virginia: Psychoneurosis Among the Armed Forces, Dr. Claude L. Neale, May 11; Anesthesia—Selection and Contraindication, Capt. James P. Curran, May 25.

At Norfolk Naval Hospital, Portsmouth, Va.: Psychosomatic Medicine, Capt. Charles A. Spangler, May 11; Drainage of the Pleura, with Particular Relation to Chest Injuries, Dr. I. A. Bigger, May 25.

U. S. MARITIME SERVICE HOSPITAL CORPSMAN TRAINING

Lieut. Fred Edwards, regional public relations officer of the U. S. Maritime Service, recently announced that, for the first time in the history of the United States Merchant Marine, trained medical persons are now sailing aboard the freighters and tankers of our merchant fleet. About two years ago War Shipping Administration officials foresaw that medical doctors would become too few to permit their assignment to sea duty aboard merchant ships. As a result of this prediction the U. S. Maritime Service hospital corpsman-assistant purser school was founded at the Sheepshead Bay training station, New York. Men who qualify are given five weeks "boot" training for their life at sea, then a twelve weeks course learning anatomy, physiology, hygiene and sanitation, first aid, emergency treatment, nursing, pharmacy and clinical laboratory. Since they have to double as pursers in the merchant marine, they next receive training to keep the ship's records. Then they graduate to assignment of four weeks duty in a marine hospital, where they proceed from department to department, applying their theoretical training. On completion of the twenty-seven weeks course the seagoing medical men are ready to "put to sea."

HOSPITALS NEEDING INTERNS AND RESIDENTS

The following hospitals have indicated to the Council on Medical Education and Hospitals that they have not completed their house staff quota allotted by the Procurement and Assignment Service:

(Continuation of list in THE JOURNAL, April 15, page 1140)

MASSACHUSETTS

Malden Hospital, Malden. Capacity, 271; admissions, 5,299. Dr. D. M. Morrill, Director (assistant resident—June 1).
St. Luke's Hospital, New Bedford. Capacity, 339; admissions, 6,144. Mr. Scott Whitcher, Superintendent (interns—October 1).

NEW YORK

Beth David Hospital, New York City. Capacity, 187; admissions, 3,985. Mr. Harold M. Salkind, Executive Director (interns).
Bronx Hospital, New York City. Capacity, 389; admissions, 8,075. Mr. William B. Seltzer, Superintendent (four interns—October 1; assistant residents, surgery—June 1, October 1).

NORTH CAROLINA

Watts Hospital, Durham. Capacity, 225; admissions, 7,475. Mr. Sample B. Forbus, Superintendent (surgical resident).

PENNSYLVANIA

Women's Homoeopathic Hospital, Philadelphia. Capacity, 200; admissions, 2,790. Miss Mary A. Smith, Administrator (assistant resident).

TENNESSEE

Nashville General Hospital, Nashville. Capacity, 305; admissions, 6,138. Mr. T. F. Connally, Administrator (2 interns, residents, medicine, obstetrics-gynecology).

WASHINGTON

Western State Hospital, Fort Steilacoom. Capacity, 3,005; admissions, 889. Dr. W. N. Keller, Superintendent (resident, psychiatry).

WEST VIRGINIA

Kanawha Valley Hospital, Charleston. Capacity, 165; admissions, 4,414. Dr. G. B. Capito, Director (intern—July 1).

COMMUNITIES IN NEED OF PHYSICIANS

In addition to the four communities mentioned in THE JOURNAL April 8, page 1068, the United States Public Health Service has announced that the following communities have applied for federal assistance in obtaining the services of physicians under the recently enacted law authorizing an appropriation of \$200,000 for the relocation of physicians:

Summerville (Green County) Kentucky.
Prentiss (Jefferson Davis County), Miss.
Glenrock (Converse County) Wyoming.

Physicians interested in locating in these communities should communicate with the Surgeon General, United States Public Health Service, Washington (Bethesda Station), D. C.

ORGANIZATION SECTION

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Changes in Status.—The President has transmitted to Congress a draft of proposed changes in the program for supplying obstetric and pediatric care to the wives and infants of servicemen, as follows: (1) Extension of the program is recommended to include the wives and infants of army aviation cadets; (2) it is proposed that not more than 4 per cent of the federal appropriation may be allotted to the states for administrative expenses on the basis of need as determined by the chief of the Children's Bureau; (3) it is proposed that the amount of federal funds to be appropriated for the continuation of the program shall be immediately available rather than available for expenditure during the fiscal year beginning July 1. H. R. 4519 has been reported to the House, authorizing an appropriation of \$1,000,000 to enable the Administrator of Veterans' Affairs to furnish seeing eye dogs for blind veterans. H. R. 4559 has passed the House, making appropriations for the Navy Department for the fiscal year ending June 30, 1945. This bill continues the provision in existing law authorizing the use of appropriations for the Naval Establishment for the pay of commissioned medical officers who are graduates of reputable schools of osteopathy.

Bills Introduced.—S. 1820, introduced by Senator Russell, Georgia, proposes a federal appropriation of \$65,000,000 for the fiscal year ending June 30, 1945 and for each fiscal year thereafter such sum as may be necessary but not in excess of \$100,000,000 for any one fiscal year to enable the Secretary of Agriculture to provide federal assistance in the maintenance,

expansion and operation of school lunch and milk programs. S. 1824, introduced by Senator Smith, South Carolina, and Senator Ellender, Louisiana, also proposes federal appropriations to establish and maintain school lunch programs to provide lunches and nutrition instruction incidental thereto for children while attending school. H. R. 4383, introduced by Representative Bennett, Michigan, proposes to extend the old age and survivors' insurance benefits of the Social Security Act to the employees of states, political subdivisions thereof and instrumentalities of states or political subdivisions, and to self-employed individuals. H. R. 4500, introduced by Representative Rogers, Massachusetts, proposes to insure the furnishing of necessary artificial limbs and other appliances to disabled World War II veterans and to provide for appropriate instruction and training in their use. H. R. 4560, introduced by Representative Gearhart, California, proposes an appropriation of \$4,000,000 to construct a veterans' hospital and home of domiciliary care in central California, with a capacity of at least 1,000 beds, with necessary auxiliary structures, mechanical equipment, domiciliary and outpatient dispensary facilities, facilities for a diagnostic center and accommodations for all personnel. H. R. 4561, introduced by Representative Barry, New York, proposes an appropriation of \$1,500,000 to construct a new veterans' hospital and diagnostic center in the county of Queens, city and state of New York. H. R. 4584, introduced by Representative May, Kentucky, proposes to remove the limitation on the right to command of officers of the Dental Corps of the Army which limits such officers to command in that corps.

WOMAN'S AUXILIARY

Arkansas

Mrs. Elizabeth Walferman, chairman of legislation in Arkansas, sent out two thousand folders to be distributed at auxiliary meetings, showing how the two billion dollars of taxes in the proposed Wagner bill would be used for political medicine.

A student loan fund is maintained for doctors in Arkansas. They have made seventy-one loans and report that all but eight have been repaid.

District of Columbia

Dr. Tibor Kereker spoke on "Current Topics" at the January meeting. Generous donations were made by the auxiliary to the "In Bed Club" of the Washington Heart Association and to the District of Columbia Tuberculosis Association.

Florida

At a recent meeting of the Duvall County auxiliary, held at the home of Mrs. Raymond H. King, an address entitled "Civilizations Disappear" was given by Mrs. Harold S. Cohn, editor of the Jacksonville Journal. At the March meeting Comdr. M. J. Capron of the United States Naval Hospital at Jacksonville spoke on "Penicillin."

Pennsylvania

Reports of the Berks, Cambria, Center, Crawford, Huntingdon, Jefferson, Lehigh, Lycoming, Mifflin and Philadelphia county auxiliaries were published in the *Pennsylvania Medical Journal*. All meetings were interesting and well attended, but a striking feature was the amount of charity done. Crawford County auxiliary made 240 garments for charity; Delaware collected books for the service men's library and gave gifts to the Medical Welfare Society and the Salvation Army; Lycoming County auxiliary purchased three war bonds and gave \$15

to the Community Chest; Philadelphia auxiliary gave \$500 to the Aid Association of the Philadelphia County Medical Association, \$50 to the War Chest, \$5 to the Baby Welfare and \$100 to fill Christmas baskets for the needy. Also the members brought toys for the children in the Philadelphia General Hospital and made 142 nightgales for the same hospital.

OFFICIAL NOTES

DOCTORS AT WAR

Radio broadcasts of Doctors at War by the American Medical Association in cooperation with the National Broadcasting Company and the Medical Department of the United States Army and the United States Navy are on the air each Saturday at 4:30 p. m. Eastern war time (3:30 Central war time, 2:30 Mountain war time and 1:30 Pacific war time).

The titles and guest speakers for the next three programs are as follows:

April 22. "Men with Purple Hearts."

Speaker, Col. Augustus Thorndike, M. C., U. S. Army, Washington, D. C.

April 29. "Winds That Kill."

Speaker, Lieut. Edward L. Corey, U. S. N., Washington, D. C.

May 6. "They Shall Walk Again."

Speaker, Col. L. T. Peterson, M. C., U. S. Army, Washington, D. C.

Doctors at War will not be on the air May 13, having relinquished its time on that date to the Office of War Information for the broadcast of a nationwide program in connection with the Cadet Nurse Corps of the U. S. Public Health Service.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Advisory Board for New Medical College.—A physicians' advisory board for the new medical college of Alabama to be erected in Birmingham was appointed March 14 by Gov. Chauncey Sparks. Members are Drs. Wilbur M. Salter, Anniston, five year term; James S. McLester, Birmingham, four year term; William D. Partlow, Tuscaloosa, two year term, and Harry Lee Jackson, Birmingham, one year term.

Program on War Casualties for Civilian Physicians.—The professional staff of Northington General Hospital, Tuscaloosa, presented a program for the Tuscaloosa and Jefferson county medical societies March 20 to show the army's medical department's progress in the treatment of war casualties. Among the speakers were:

Lieut. Col. I. William Nachlas, M. C., Gun Shot Wounds.
Capt. Frederick T. Becker, M. C., Penicillin.
Lieut. Col. Thomas R. Wright, M. C., Pilonidal Cyst.
Lieut. Col. Nicholas Michael, M. C., Psychoneurosis.

John A. Andrew Clinical Meeting.—The John A. Andrew Clinical Society held a clinical session with the John A. Andrew Memorial Hospital at Tuskegee Institute, April 2-8. Among the speakers were:

Dr. Charles F. Sherwood, St. Louis, Plastic Repair of Weblike Scars.
Dr. Jacob Daley, New York, Typical Rhinoplasty.
Roscoe C. Brown, D.D.S., Specialist, U. S. Public Health Service, Address on Public Health.
Drs. Ulysses Grant Dailey and Leonidas H. Berry, Chicago, Medical and Surgical Management of Peptic Ulcer.
Dr. Wallace Byrd, Norfolk, Va., Syphilis as a Cause of Selective Service Rejection of Negro Youth.

There will be two symposiums, one on flight surgeon's activities, conducted by Lieut. Col. Richard C. Cumming, M. C., Major Harold E. Thornell, M. C., and Capt. Leroy R. Weeks, and one on mental hygiene conducted by Dr. Prince P. Barker, Tuskegee.

DISTRICT OF COLUMBIA

Meningitis Quarantine Ended.—The use of sulfonamide drugs recently made possible the waiving of the usual twenty-one day quarantine for persons exposed to meningitis. A three day quarantine of 300 women at Arlington Farms, Va., was in effect. Newspaper reports stated that four deaths had occurred in the outbreak. The first case was discovered in Louisiana Hall at Arlington Farms accommodating 334 women government workers. One woman died while being transferred from Arlington Farms to a hospital in Washington, a year old child died at Children's Hospital, Washington, one woman died in Suburban Hospital, Bethesda, Md., and another woman died in Freedmen's Hospital, Washington.

Physician Receives Spingarn Medal.—Dr. Charles R. Drew, assistant professor of surgery, Howard University College of Medicine, Washington, has been awarded the Spingarn Medal for 1943 for the highest and noblest achievement by an American Negro. The award, which was announced by the National Association for the Advancement of Colored People, went to Dr. Drew for his work while medical supervisor of a blood transfusion project sponsored jointly by the Blood Transfusion Association and the American Red Cross of New York. Dr. Drew, together with Dr. John Scudder, New York, was instrumental in developing techniques for the mass collection of blood plasma and the preservation of plasma for shipment overseas. The work was carried on during the years 1938-1941.

ILLINOIS

Rocky Mountain Spotted Fever.—A 23 year old man was reported to be ill with Rocky Mountain spotted fever in Alton, March 23.

Chicago

Northwestern Alumni Luncheon.—Northwestern University medical alumni will convene at a luncheon in the Palmer House May 17. The luncheon will be a feature of the annual meeting of the Illinois State Medical Society.

Course in Neuromuscular Anomalies of the Eyes.—The twelfth semiannual postgraduate course in neuromuscular anomalies of the eyes at the Children's Memorial Hospital will be conducted May 7-12 by Dr. George P. Guibor. Additional information may be obtained from the secretary of the course, 707 Fullerton Avenue, Chicago 14.

The Gehrman Lectures.—Dr. Harold S. Diehl, dean of the medical sciences, University of Minnesota Medical School, Minneapolis, will deliver the Gehrman Lectures for 1943-1944 at the University of Illinois College of Medicine May 17-19. His first lecture will be devoted to the cause and epidemiology of the common cold and the second to its prevention and treatment. The third lecture will be entitled "Some Recent American Epidemics."

Relocating Service Men and War Workers.—A conference will be held at the Drake Hotel, April 28-29, devoted to "Reabsorbing and Relocating Service Men and War Workers," under the auspices of the Society for the Advancement of Management. Included among the speakers will be representatives of the various phases of industry and some of the topics for discussion are guiding the service man's return to industry, organizing for relocation, problems of retraining, and the value of the job. A dinner session will be addressed by F. H. Kirkpatrick, manager of personnel administration, Radio Corporation of America, Camden, N. J., on "The Human Factor in Industrial Reconversion." One luncheon session will be addressed by a returned service man on "What the Man at the Front Thinks About His Return to Industry." Another luncheon session will be addressed by Charles W. Beese, M.E., head of the department of general engineering, Purdue University, Lafayette, Ind., on "The Influence of the War Effort on Management Education."

LOUISIANA

State Medical Meeting.—The sixty-fifth annual meeting of the Louisiana State Medical Society will be held at the Roosevelt Hotel, New Orleans, April 24-26, under the presidency of Dr. Charles C. deGravelles, New Iberia. Among the speakers on the program will be:

Dr. Waldo L. Treuting, New Orleans, and Byron J. Olson, P. A. Surg., U. S. Public Health Service, Clinical and Epidemiologic Features of an Epidemic of Severe Pneumonitis in Southwestern Louisiana.
John A. Lane, Surgeon, U. S. Public Health Service, Rupture of Intervertebral Disk.
Dr. Edgar Burns, New Orleans, Prostatic Obstruction and Some of Its Common Complications.
Dr. F. Walter Carruthers, Little Rock, Ark., Management of Shaft Fractures of the Long Bones.
Dr. Robert A. Katz, New Orleans, Psychosomatic and Medical Aspects of Peptic Ulcer.

At the president's dinner Tuesday evening Dr. Felix J. Underwood, Jackson, Miss., will deliver the annual oration. A feature of the state meeting will be a centennial exhibit reviewing the history of the *New Orleans Medical and Surgical Journal*. The woman's auxiliary to the state association will also hold its annual meeting at the Roosevelt Hotel, April 24-25.

MARYLAND

State Medical Meeting.—The Medical and Chirurgical Faculty of the State of Maryland will hold its annual session in Osler Hall, Baltimore, April 25-26, under the presidency of Dr. Jacob W. Bird, Sandy Spring, who will deliver an address entitled "Do We Need Federal Medicine?" Among other speakers on the program will be:

Dr. William H. F. Warthen, Towson, A County Health Program in War Time.
Dr. Arthur M. Shipley, Baltimore, Report of the Committee on Medical Service and Public Relations Regarding the Wagner-Murray-Dingell Bill.
Dr. Harry Arthur Cantwell, North East, The Toxic Effects of TNT and the Care of Workers in a Munition Factory.
Dr. Dexter M. Bullard, Rockville, The Practitioner as a Psychiatrist.
Dr. Albert Austin Pearre, Frederick, Fever of Obscure Origin.
Dr. Perry F. Prather, Hagerstown, Evaluation of the Pneumococcus Antigen as Measured by Pneumonia Prophylaxis in Maryland.

Dr. Allen O. Whipple, Valentine Mott professor of surgery, Columbia University College of Physicians and Surgeons, New York, will deliver the Trimble Lecture on "Hyperinsulinism in Relation to Pancreatic Tumors." A round table luncheon will be conducted by Drs. James G. Arnold Jr. and Bartus T. Baggott, Baltimore, on neurosurgery and tuberculosis respectively.

MASSACHUSETTS

Administrative Appointment at Harvard.—Alfred Le Roy Johnson, D.M.D., professor of clinical dentistry at Harvard University, has been appointed administrative officer of the new School of Dental Medicine at Harvard and associate dean of the faculty of medicine. Dr. Johnson graduated at Tufts College Dental School in 1904. He has served as professor of orthodontics at Tufts College, University of Michigan, University of Pennsylvania and as research associate in experimental genetics at Cornell University Medical College, New York. He was named to his professorship at Harvard in 1942.

NEBRASKA

State Medical Meeting.—The Nebraska State Medical Association will hold its annual meeting at the Hotel Fontenelle, Omaha, May 1-4, under the presidency of Dr. Albert L. Cooper, Scottsbluff. Among the out of state speakers will be:

- Dr. Hans C. S. Aron, Chicago, Some Clinical Implications of Recent Advances in the Knowledge of the Vitamins.
Dr. Oliver E. Van Alyea, Chicago, Modern Trends in Sinus Therapy.
Major Oliver R. McCoy, M. C., Public Health Importance of Tropical Diseases in Returned Soldiers.
Dr. Alfred W. Adson, Rochester, Minn., The Federal Challenge to the Practitioner of Medicine.
Dr. Clarence Dennis, Minneapolis, Surgical Treatment of Upper Abdominal Pain.
Dr. Will F. Lyon, Chicago, The Holding Power of Various Types of Screws in Bone.
Dr. Guy A. Caldwell, New Orleans, The Influence of Bacteriostatics and Anti-Biotics in the Treatment of Compound Fractures and Wounds.
Dr. Guy W. Leadbetter, Washington, D. C., The Problem of the Fractured Hip.
Dr. Willard R. Cooke, Galveston, Texas, A Study of Gonorrhea in Women.
Dr. Frederick H. Falls, Chicago, Abortion.

At an army session Lieut. Col. Nathan K. Jensen, M. C., will speak on "War Wounds of the Extremities," Lieut. Col. Edward B. Badger, M. C., "Medical Problems of Selective Service" and Lieut. Col. Edgar van Nuys Allen, M. C., will discuss "Functional Somatic Disorders in the Army" from the consideration of the internist and Lieut. Col. Clarke H. Barnacle, M. C., from the viewpoint of the psychiatrist.

NEW YORK

Personal.—Dr. Howard P. Carpenter has resigned as director of the laboratory of the Poughkeepsie board of health, effective May 1. Newspapers indicated that Dr. Carpenter would also resign as director of the laboratory of the Hudson River State Hospital and as deputy county medical examiner. He plans to go to Vermont, it was stated. Dr. Carpenter resigned as secretary of the Dutchess County Medical Society in 1941 after holding the position for twenty-seven years.—Dr. Bruno Leichtentritt has been appointed medical director of the Irvington House, an institution for the care of children with rheumatic heart disease in Irvington. Dr. Leichtentritt had been for more than five years a fellow of the Children's Fund of Michigan at the William J. Seymour Hospital, Eloise, according to *Detroit Medical News*.

Research Professorship in Pediatrics.—Dr. Edward M. Bridge, associate in pediatrics, Johns Hopkins University School of Medicine, Baltimore, has been named to a new research professorship in pediatrics at the University of Buffalo School of Medicine and in charge of the Statler pediatrics research department in the Children's Hospital, Buffalo. A floor of the hospital is being remodeled to house the laboratories, which have been provided by a grant of the trustees of the late E. M. Statler. Dr. Bridge will conduct research in drugs used in the treatment of epilepsy, the water and sugar requirement of sick children, the care of premature infants and other pediatric problems. At the university he will encourage and promote research in the diseases of children and stimulate research among medical students. Other changes at the school include the appointment of Oliver P. Jones, Ph.D., assistant professor of anatomy, as head of the department of anatomy, succeeding Donald Duncan, Ph.D.

New York City

Phi Delta Epsilon Lecture.—Dr. Arthur M. Fishberg will deliver the annual Phi Delta Epsilon lecture at the Long Island College of Medicine, Brooklyn, April 27, on "Recent Advances in Hypertension."

Changes in Sanitary Code.—A recent amendment to the city sanitary code provides that in no case shall a person previously convicted of a prostitutional offense be released from detention in a hospital designated by the city department of health unless such a person is no longer infected with a venereal disease in a communicable form. An additional amendment includes meningococcus meningitis (epidemic cerebrospinal meningitis) and typhus fever on a list of causes of death requiring the body of the deceased to be immediately and permanently sealed in a casket before removal from the place of death. Another amendment stipulates that all forms of plague shall be considered reportable diseases.

Gift of Apothecary Shop to Columbia.—A fully equipped "apothecary's shop of the eighties," complete with prescription counter, ointment jugs, iron mortars and shelves of samples of the "patent medicine" era, was presented formally to Columbia University College of Pharmacy by Arthur J. Kinsman, trustee of the school. It was installed as a permanent teaching exhibit in the college. According to the New York

Times, the prescription counter of the old store once stood in Roediger's Drugstore at 46 Market Street, which opened in the city in 1832. A wooden safe of the same age, which was purchased by the college of pharmacy in 1843, stands in a corner of the store. The *Times* states that the old "patent medicines," including "positive pain cure," gout remedies, magic oils, chill tonics and hair growers, are also included. A cordial for babies carries on its label "cure for colic and teething." A large porcelain jar with a perforated top is labeled "leeches" and was used to carry a ready stock of living cures for black eyes. In making the presentation to the college, Mr. Kinsman referred to the pharmaceutical products as reminders of the "patent medicine" era of the 1870's, "those glorious days of the wouldbe cure-alls, good for man or beast."

NORTH CAROLINA

Committees Named to Work with New Medical Care Commission.—On March 11 Governor Broughton announced the appointment of six subcommittees to work with the new North Carolina Hospital and Medical Care Commission. The committees are four year medical school for the University of North Carolina and hospital facilities, Dr. Paul P. McCain, Sanatorium, chairman; hospital and medical care for rural population, Thomas J. Pearsall, Rocky Mount, chairman; hospital and medical care for industrial and urban population, Charles A. Cannon, Concord, chairman; special needs of the Negro population, C. C. Spaulding, Durham, chairman; mental hygiene and hospitalization, Dr. James W. Vernon, Morganton, chairman, and hospital and medical care plans in other states, Dr. William M. Coppridge, Durham, chairman. The program of the newly appointed commission is designed to see that "no person in North Carolina shall lack adequate hospital care or medical treatment by reason of poverty or low income" (THE JOURNAL, March 25, p. 939).

State Medical Meeting.—The ninety-first annual session of the Medical Society of the State of North Carolina will be held at the Carolina Hotel, Pinehurst, May 1-3, under the presidency of Dr. James W. Vernon, Morganton. The preliminary program includes the following speakers:

- Col. Burr N. Carter, M. C., The Recent Trends in the Care of the War Wounds.
Judge L. R. Varser, Lumberton, Socialized Medicine From a Layman's Point of View.
Dr. Clarence H. Smith, New York, Ménière's Symptom Complex.
Dr. James W. White, New York, Ocular Muscle Paralysis—Their Diagnosis and Treatment.
Dr. Louis K. Diamond, Boston, Transfusion Reaction Due to the Rh Blood Type.
Dr. Neka B. Hon, Bethesda, Md., Recent Experiences in the Intensive Treatment of Syphilis.
Dr. James E. Paullin, Atlanta, Ga., President of the American Medical Association, Medical Planning for the Postwar Period.

At the president's dinner, Strickland Gillilan, Washington, D. C., author of the poem "Off Agin, On Agin, Gone Agin, Finnigin," will be the guest speaker.

OHIO

Food Information Center.—The Cleveland Health Council, in cooperation with the Cleveland Health Museum, has established a food information center at the museum. A nutritionist is available at the museum one evening a week to answer questions on food and food problems.

State Medical Meeting in Columbus.—The ninety-eighth annual meeting of the Ohio State Medical Association will be held at Neil House, Columbus, May 2-4, under the presidency of Dr. Clifford C. Sherburne, Columbus. Among the speakers on the program will be:

- Dr. Paul H. Holinger, Chicago, Cine-Bronchoscopy-Kodachrome Visualization of Endobronchial Pathology.
Dr. Oliver W. Hosterman, Columbus, Influenzal Meningitis.
Dr. Noel A. Gillespie, Madison, Wis., Factors that Influence the Success of an Anesthetic Administration.
Dr. Alexander A. Weech, Cincinnati, Hyperbilirubinemia in the New-born.
Dr. Edward Harlan Wilson, Columbus, Treatment of Fractures as Related to Functional Recovery.
Anton J. Carlson, Ph.D., Chicago, Fatigue.
Melvin H. Knisley, Ph.D., Chicago, Motion Picture—Knowless Malaria in Rhesus Monkeys.
Dr. Edward L. Turner, Nashville, Tenn., The Dysenteries.

Special features of the meeting will include a discussion on functional and organic diseases of the gastrointestinal tract by Drs. Andrew C. Ivy, Chicago, and Arthur W. Allen, Boston, and special quiz discussion sessions on medicine, including tropical medicine, psychiatry and occupational diseases. At the annual dinner Wednesday evening Mr. Grove Patterson, editor, Toledo *Blade*, will give the principal address, on "Britain in Wartime." Other groups meeting during the annual session will include the woman's auxiliary to the state association, the Ohio Society of Anesthetists, the Ohio chapter of the American College of Chest Physicians and the Ohio State Radiological Society.

OKLAHOMA

Paul Fesler Appointed Temporary Executive Secretary.—Mr. Paul H. Fesler, formerly superintendent of the University Hospitals, Oklahoma City, and of the University Hospitals, Minneapolis, has been named on a temporary basis to act as executive secretary during the absence of Mr. Richard H. Graham, according to the state medical journal. Mr. Fesler was once superintendent of the Wesley Memorial Hospital, Chicago, and has served as president of the American Hospital Association.

Conference on Poliomyelitis.—At the suggestion of crippled children's agencies in Texas, Oklahoma and Kansas, three states seriously affected by the poliomyelitis epidemic of 1943, a conference on basic planning for dealing with such epidemics was held in cooperation with the U. S. Children's Bureau in Oklahoma City, February 23-24. Dr. Abram L. Van Horn, assistant director for crippled children, division of health services of the Children's Bureau, U. S. Department of Labor, was chairman of the conference.

VIRGINIA

Special Society Meeting.—The Virginia Society of Ophthalmology and Oto-Laryngology will be addressed at its twenty-fifth annual meeting in Lynchburg, April 29, among others, by Drs. John H. Dunnington, New York, on "Complications of Cataract Extraction" and Arthur T. Ward Jr., Baltimore, "Local Use of Sulfadiazine, Penicillin, Tyrothricin and Radon in the Field of Otolaryngology." Dr. Emmett T. Gatewood, Richmond, is president of the group and Dr. Meade C. Edmunds, Petersburg, is secretary.

The Stuart McGuire Lectures.—The fifteenth annual Stuart McGuire lectures were delivered at the Medical College of Virginia, Richmond, April 5-6. Dr. Winfred Overholser, superintendent, St. Elizabeths Hospital, Washington, D. C., spoke on "Modern Trend in Psychiatry" and Lieut. Col. William C. Menninger, chief of the army's division of neuropsychiatry, "Psychiatric Problems in the Army." The lectures were given in conjunction with a postgraduate clinic devoted this year to a series of psychiatric subjects.

WISCONSIN

Winners in Essay Contest.—The Milwaukee Academy of Medicine announces that first prize in the Horace Manchester Brown Memorial Essay Contest went to Dr. Robert H. Feldt, Milwaukee, for his paper entitled "Sulfanilamide as a Prophylactic Measure in Recurrent Rheumatic Fever: A Controlled Study Involving 131 'Patient-Seasons.'" Second prize went to Dr. Nathan M. Grossman, Milwaukee, for his paper on "The Left Auricle." The prizes were \$100 and \$50 respectively. The academy also announces that no award was made for the Rogers Memorial Essay Contest because, in the opinion of the judges, no papers were deemed worthy (THE JOURNAL, June 19, 1943, p. 553).

GENERAL

Examinations in Internal Medicine.—The American Board of Internal Medicine will hold oral examinations in Chicago, June 8-10. The closing date for the acceptance of applications is May 20. Communications should be addressed to the assistant secretary-treasurer of the board, Dr. William A. Werrell, 1301 University Avenue, Madison 5, Wis.

Association of Basic Science Boards Organized.—The American Association of Basic Science Boards was organized at a meeting in Chicago, February 15, with Orin E. Madison, Ph.D., Detroit, of the Michigan board, as president. Other officers include Charles D. Byrne, Ed.D., Oregon board, Eugene, vice president; Charles H. Carter, D.Sc., Iowa board, Fairfield, secretary-treasurer, and John S. Latta, Ph.D., Nebraska board, Omaha, and Rev. Nicholas H. Serron, O.P., Rhode Island board, Providence, executive committee.

Membership of Board of Neurological Surgery.—At a meeting of the American Board of Neurological Surgery in New York, March 26, it was voted unanimously that the number of members of the board nominated by the Society of Neurological Surgeons should be reduced from five to four and that the American Academy of Neurological Surgery should be invited to nominate one of their neurosurgical members to the board for a term of office, to begin in the summer of 1944.

Association of Cereal Chemists.—The thirtieth annual meeting of the American Association of Cereal Chemists will be held at the Nicollet Hotel, Minneapolis, May 23-26. A feature of the meeting will be a symposium on protein nutrition conducted by Richard J. Block, Ph.D., New York, "Eval-

uation of Food Proteins from the Essential Amino Acid Composition"; Herman J. Almquist, Ph.D., Berkeley, Calif., "Effective Use of Feed Proteins in Nutrition of the Chick," and Dr. Paul R. Cannon, Chicago, "The Nutritional Assay of Proteins by Means of the Adult Hypoproteinemic Rat."

Pan American Conference of National Directors of Health.—The fifth Pan American Conference of National Directors of Health will be held in Washington, April 22-29, to discuss wartime and postwar health programs. The subjects include air navigation quarantine, immigration, improved national and international disease reporting, aerial navigation, port sanitation, quarantine regulations and the adoption of an international health certificate. One feature of the meeting will be the preparation of a program for the XII Pan American Sanitary Conference, to be held in Caracas, Venezuela, in 1946. Health and hygiene authorities of the Latin American countries will be represented. Canada will also be represented.

Fund for Research in Psychosomatic Medicine.—The National Committee for Mental Hygiene announces the establishment of a fund for research in psychosomatic medicine to stimulate and subsidize research in the psychosomatic aspects of the diseases chiefly responsible for disability and death. The fund will be directed by Dr. Edward Weiss, Philadelphia, and administered under the direction of Dr. George S. Stevenson, New York, medical director of the National Committee for Mental Hygiene. Projects will be considered by a committee composed of Drs. Charles A. Aldrich, Rochester, Minn., Franz Alexander, Chicago, Stanley Cobb, Boston, John Romano, Cincinnati, and Lieut. Col. William C. Menninger. Additional information may be obtained from Dr. Weiss, 269 South 19th Street, Philadelphia 3.

Borden Prize Awarded to William Clark.—At the meeting of the American Chemical Society in Cleveland, April 5, the Borden Company Prize for 1944 of \$1,000 for research in the chemistry of milk was presented to William Mansfield Clark, Ph.D., DeLamar professor of physiologic chemistry at the Johns Hopkins University School of Medicine, Baltimore, and chairman of the division of chemistry and chemical technology at the National Research Council, for his contributions to the application of acid-base theory to laboratory and plant practice. Science reports that, as a result of his work and writings, the old haphazard and often irrational procedures in the dairy industry and other industries have been fruitfully transformed during the past years to precise scientific manipulations.

Dr. Strode Succeeds Wilbur Sawyer at Rockefeller Foundation.—Dr. George K. Strode, associate director of the International Health Division of the Rockefeller Foundation in charge of the division's work in Europe, has been appointed director of the division to succeed Dr. Wilbur A. Sawyer, who will retire, effective September 1. Dr. Sawyer, who graduated at Harvard Medical School, Boston, in 1906, was appointed state director of the International Health Board in 1919. He has served as assistant regional director for the east, director of public health laboratory service, associate director of the International Health Division and, since 1935, director. Dr. Strode graduated at the University of Pennsylvania School of Medicine, Philadelphia, in 1912, receiving his master's degree in public health at Harvard in 1927. He has been a member of the International Health Division of the foundation since 1920, having been chosen a member for one year in 1916. He was assistant director for activities in Europe and the Near East from 1927 to 1938, when he became associate director. He was chairman of the Paris office from 1932 until 1938.

Nutrition Grants.—Grants totaling \$131,000 for research projects in nutrition were approved by the board of trustees of the Nutrition Foundation at a meeting in New York, April 5. The grants are distributed among twenty-three colleges and universities in the United States and Canada and include renewal of grants for thirty-one research projects already in progress and three additional grants for studies at Harvard, Yale and Cornell. According to a release from the foundation, grants having greatest value thus far were "those dealing with army rations, human protein requirements, maternal and infant nutrition, dental caries and human vitamin requirements." The new grants authorized at the recent meeting include:

Harvard University, Cambridge, for training physicians in the human and public health aspects of nutrition.

Yale University, New Haven, Conn., in support of maternal and infant nutrition studies, based on carefully controlled nutrient intakes of primates (monkeys), other animals having been found not so satisfactory for the study of numerous human problems such as dental caries, physical deformities or functional impairment.

Cornell University, Ithaca, N. Y., for study of the biochemical mechanism of converting starches and sugar into fat.

Meeting of Bacteriologists.—The forty-fifth annual meeting of the Society of American Bacteriologists will be held at the Hotel Pennsylvania, New York, May 3-5, under the presidency of Ira L. Baldwin, Ph.D., Madison, Wis. Among the speakers will be:

- Merton F. Uter, B.A.; Lester O. Krampitz, Ph.D., and Chester H. Werkman, Ph.D., Ames, Iowa, Oxidation of Acetyl Phosphate by *Micrococcus Lysodeikticus*.
Dr. Harold E. Pearson, Ann Arbor, Mich., The Distribution of Influenza Virus Type A in Infected Eggs and the Survival of Virus Under Certain Conditions of Storage.
Gordon C. Brown and Dr. Thomas Francis Jr., Ann Arbor, Mich., Embryonic Chick Antigens for Complement Fixation with the Viruses of Eastern and Western Equine Encephalomyelitis.
Maurice R. Hilleman, S.B., and Dr. Francis B. Gordon, Chicago, Immunological Studies on the Relationships of the Psittacosis-Lymphogranuloma Group of Viral Agents.
Reuben L. Kahn, Sc.D., and Elizabeth B. McDermott, Ann Arbor, The Verification Test in Postvaccination Cases.
Albert Milzer, Ph.D., Dr. Philip Lewin and Dr. Sidney O. Levinson, Chicago, Studies on the Influence of Fatigue, Chilling and Trauma on Experimental Poliomyelitis.
Selman A. Waksman, Ph.D., New Brunswick, Mode of Action of Antibiotic Substances.
Albert C. Hunter, Ph.D., Washington, D. C., Standardization of Assay of Penicillin.
Dr. William S. Tillett, New York, An Analysis of the Therapeutic Action of Penicillin Based on the Clinical Response of Patients and Correlated Laboratory Findings.
Elaine Uppdyke, M.S., and Martin Frobisher Jr., Sc.D., Baltimore, Group B Streptococci and Malignant Diphtheria.

There will be round table discussions on recollections of the early days of bacteriology in New York City, problems concerning anaerobic bacteria, taxonomy and primary atypical pneumonia.

LATIN AMERICA

Health Activities in Latin America.—*Cinchona*.—Studies to determine the practicability of developing new cinchona plantations in Mexico are being conducted by the department of health, according to the *New York Times*, April 9. About 60,000 cinchona plants are under cultivation in the state of Chiapas. Production of quinine eventually may be sufficient to meet all domestic requirements and provide an export surplus, it was stated. Important progress has been made in the cooperative hemispheric effort to cultivate quinine-yielding cinchona, according to William C. Davis of the staff of the United States Office of Foreign Agricultural Relations in the *Inter-American Economic News*. Quinine supplies for the United Nations are being obtained from Guatemala, Venezuela, Colombia, Ecuador, Peru and Bolivia, which countries, with Mexico, Costa Rica and Brazil, are cooperating with the United States to develop in the Western Hemisphere a sound cinchona industry. Colombia has contributed more bark from wild or native stands during the past year than any other country in this hemisphere. It was stated that in Colombia the bark from a related plant, botanically known as *Remijia*, contains enough quinine to make its harvest profitable under existing conditions. In Brazil cinchona production is still in the experimental stage. Small plantings have been made in the mountainous regions bordering the state of Minas Gerais, and cinchona seedlings supplied by the United States have been put out at Campinas and Baracca. The United States, through the department of agriculture and the foreign economic administration, is cooperating with all these cinchona producing countries. The foreign economic administration is concerned with the procurement of cinchona and such work as will expedite availability of high quality bark, and the department of agriculture is aiding through research, technical advice and demonstration in the growing of the plants. It is also sending quality seedling stock to the most promising production areas.

Physician Heads Identification Division.—Dr. Hubert Wallau, who is now in the United States studying traumatic surgery under the auspices of the Institute of Inter-American Affairs, an agency of the Office of Inter-American Affairs, is head of the identification division in Rio Grande do Sul, Brazil. Dr. Wallau is studying at the Boston City Hospital. In Brazil he is a member of the staff of the Santa Casa de Misericordia Hospital in Porto Alegre.

Society News.—Drs. Egidio S. Mazzei and Carlos Reussi were elected president and secretary, respectively, of the Society of Internal Medicine of Buenos Aires for 1944.—Dr. Ramón N. Ibarra Perez was chosen president and Dr. Guillermo Gonzalez Peris secretary of the Cuban Society of Dermatology and Syphilology for 1944.

New Publication.—The Argentine Psychoanalytic Association recently began the publication of its official organ, *Revista de psicoanalisis*.

Graduate Course in Legal Medicine.—A two year postgraduate course in legal medicine has been created by the Faculty of Medicine at the University of La Plata, Buenos Aires, Argentina, for physicians who wish to become specialists in this field. The course will be under the direction of Dr. José

Belbey, professor of legal medicine of the Faculty of La Plata School of Medicine and adjunct professor of medicine in the School of Medicine of Buenos Aires, and includes lectures, seminars and actual clinical work. During the first year the curriculum includes legal medicine, clinical psychiatry, medicolegal toxicology, legal medicine and occupational diseases. The second year encompasses forensic psychiatry, criminology and principles of penal law, medicolegal necropsy and medicolegal aspects of workmen's compensation. Those completing the course will receive a specialist's diploma, according to the *Journal of Criminal Psychopathology*.

Hospitals for the Amazon.—Harold B. Gotaas of the Health and Sanitation Division, Office of Inter-American Affairs, has recently prepared a review on the hospital development program in Latin America entitled "Hospitals for the Amazon." The program, he points out, is being done as part of inter-American health and sanitation measures recommended by the Rio de Janeiro conference of American Foreign Ministers in January 1942, which measures have evolved into a continental program to improve health and sanitation conditions in areas important to the development of hemisphere resources and defenses. Nineteen of the American republics, including the United States, are participating. Mr. Gotaas, who is a sanitary engineer, discusses the project as it is carried out in the Amazon Basin, covering the territory of Brazil, Bolivia, Peru, Ecuador, Colombia and Venezuela. While this area has great tropical forests, wood is not suitable for the building materials, clay and brick being used instead, he says. New construction included a 20 bed hospital in Guayaramerin and in Pucallpa, Peru. In Iquitos a 100 bed hospital was one of the first projects in the Peruvian health program, which includes a 20 bed children's ward, 20 bed women's ward, 20 bed men's ward, a surgical section with operating and x-ray room, administrative wing with outpatient department, and kitchen and general service wing, water and sewerage facilities. At Santarem a 50 bed hospital, also of tile and brick construction, contains operating rooms, outpatient department and pharmacy. In addition many health centers and dispensaries are being erected.

New Monthly Epidemiologic Report.—With the March issue the *Monthly Report on Epidemiological and Vital Statistics* begins its regular appearance under the auspices of the Pan American Sanitary Bureau, Washington 6, D. C. The report replaces the tables on pestilential diseases which were published in the *Boletín* of the Pan American Sanitary Bureau. The purpose of the publication is to convey, in the quickest possible manner, to the national and international public health organizations, as well as to all other interested parties, the available information on the incidence and mortality of certain communicable diseases, as well as other biostatistical data on various countries, particularly those in the Western Hemisphere.

Personal.—Dr. George C. Dunham, executive vice president of the Institute of Inter-American Affairs, and assistant coordinator in charge of the basic economy department, Office of the Coordinator of Inter-American Affairs, has been promoted from brigadier general to major general, medical department, A. U. S., with rank from February 22. According to the *Newsletter*, Division of Health and Sanitation, of the coordinator's office, Clair E. Turner, Dr.P.H., of the professional training and health education section of the division recently spent time in Brazil, Peru and Chile to consult with respective field parties on health education programs.

FOREIGN

Typhus Epidemic Among Yemenite Refugees.—Professor I. J. Kligler, professor of bacteriology and hygiene, Hebrew University of Jerusalem, left with three Palestinian Jewish nurses for Aden by plane in February to organize medical relief for 1,600 Yemenite refugees, among whom a typhus epidemic has broken out. The mission was sent at the request of the Aden government, according to the *New's Bulletin* published by the American Friends of the Hebrew University.

CORRECTION

Allergy to Lan-O-Kleen Soap.—In THE JOURNAL, Dec. 11, 1943, page 991, appeared an abstract of a workman's compensation case regarding an allergy to Lan-O-Kleen soap, which a workman was required to use in the course of his employment. The abstract of the case emphasized the fact that the employee had used the lava soap for six or seven years and did not develop an allergy until he adopted the Lan-O-Kleen soap. The concluding sentence of the next to last paragraph read "Lava soap was a poison to the workman, and his injury was compensable." In this sentence the words "lava soap" should have been "Lan-O-Kleen soap."

The National Health Service: Attitude of the British Medical Association

A mass meeting of the Metropolitan Counties Branch of the British Medical Association was held recently to hear an address by Dr. Charles Hill, secretary, on the White Paper, which he described as the government's first thoughts on the Beveridge scheme to provide a comprehensive medical service for all who wanted it, irrespective of income limit. Dr. Hill said he believed that the general reaction of the profession to the three "freedoms" set out in the paper was that they were worthy of full support, but the real test would be the extent to which these freedoms found expression in the administrative machinery and arrangements. They are: 1. Freedom for people to use or not to use the facilities; no compulsion for either patient or doctor; no interference in the making of private arrangements at private cost, if any one prefers to do so. 2. Freedom for people to choose their medical advisers. 3. Freedom for the doctor to pursue his professional methods in his own way. The personal doctor-patient relation was to be preserved and the whole service founded on the "family doctor" idea.

The proposal for a corporate body, Dr. Hill pointed out, was not accepted by the government. But whereas comprehensive service was preached in all other directions, he said, there was no comprehensive service planned for the center; rather the medical services would remain distributed among a multitude of government departments. An advisory body, the Central Services Council, was to be set up, consisting of both medical and lay members appointed by the minister, not specially elected for the purpose by the professional organizations. This, Dr. Hill thought, was wrong.

At the periphery, he continued, instead of the hoped for fundamental recasting of local government there was a compromise. There would be not fewer local authorities but more. The hospital services had to be dealt with regionally, but Dr. Hill thought it was regrettable that in creating the new type of body, the Joint Authority, the government had been unwilling to dilute the democratic principle by including, in the public interest, some nonelected professional and expert members.

On administration as a whole he said that the arrangements spit the profession into four groups: general practitioners in separate practice, general practitioners in health center practice, consultants appointed by voluntary hospitals and consultants appointed by local authorities. There was also a group whose position, Dr. Hill felt, must be viewed with considerable anxiety—their colleagues of the public health service. Dr. Hill also had misgivings as to the health centers. The Association had urged that these should be initiated for a period of experiment with a view to discovering the right type of group practice. This might be (1) the center with general practitioner beds, (2) the diagnostic center, concentrating on special methods of investigation and possibly treatment, (3) the true health center, in which both preventive and curative services are integrated or (4) the communal surgery. The last and least advanced of these types was adopted in the White Paper.

When practitioners participate in group practice health centers, remuneration is to be by salary or similar arrangement. The government needed to be converted on that issue, Dr. Hill thought. He saw nothing inconsistent with group practice in continuing a method of remuneration within the health center which bore a relationship to the amount of work done. On the whole, he said, there was much that was sound and attractive in the health center conception, but the attitude of the profes-

sion must be tinged with caution lest, without sufficient experiment, the project be pushed by those who sought not health centers but a particular form of salaried employment under local authorities.

Two things, he said, made Dr. Hill suspicious. The consent of the Central Medical Board was necessary before new practitioners could participate in the service or existing practitioners start in new areas. The argument was that practitioners must be prevented from going into areas already sufficiently staffed. There might be a case for that, Dr. Hill acknowledged, but the White Paper advocated that such approval must be given to every practitioner desiring to enter the public service. The board is to be a civil service structure under the general direction of the minister. Again, newly qualified doctors will be required to give full time in the public service in their early years if necessary. The association, Dr. Hill felt, was not prepared to accept this form of civil direction and conscription. He pointed to the danger that by administrative procedure, bit by bit, the one thing to which the profession was fundamentally opposed—a whole time salaried service—could be introduced.

The proposals of the White Paper will soon be discussed in Parliament. It is evident that any opposition from the medical profession will be in connection with such details as are mentioned here. Every proposal is open to debate before it becomes law.

BOLIVIA

(From Our Regular Correspondent)

La Paz, Feb. 21, 1944.

Typhoid Epidemic in La Paz

During the last two months there has been a severe epidemic of typhoid in Bolivia's largest city, La Paz. A minor epidemic developed in Cochabamba. Official estimates, based on doctors' reports, indicate that there have been about 200 cases and some 50 deaths, but private estimates place both figures about four times as high because of hidden cases. Lack of sanitary supervision over the open market sellers of vegetables, fruit and meat, the lack of good general hygienic conditions and the deficient sewage disposal systems in some suburbs are chiefly responsible for the fast spread of the epidemic, which apparently spreads from undetected sources every few years. Local health authorities have proceeded with immediate vaccination with Bolivian made vaccines, but out of a population of about 300,000 people only a few presented themselves. Also the Servicio Cooperativo Interamericano de Salud Pública, supported by the office of the coordinator of Inter-American affairs, vaccinated with American made vaccines, but it seems that a large number of people did not report for revaccination. The General Hospital isolation ward, with 51 beds available, soon became overcrowded. Fortunately, La Paz drinking water is acid, with an estimated pH of from 5 to 6, so that no contamination occurred this way. The public was instructed by newspapers and radio about the safety measures to be adopted. Lack of available funds makes it hard to carry out any thorough measures against future epidemics of this kind.

A Branch of the International College of Surgeons in Bolivia

On January 12 the Bolivian branch of the International College of Surgeons was founded in La Paz in the presence of the former United States ambassador to Bolivia, Mr. Pierre de Boale, and the vice president of La Paz University, Dr. Ernesto Navarro. The chairman of this new institution, Dr. Enrique St. Loup, in his inauguration speech mentioned that the Bolivian branch of the institution was founded in response to an invitation received a year ago from the headquarters of the college in Washington, D. C. The program of this first meeting included the exhibition of a La Paz film showing the different phases of a subtotal thyroidectomy.

Deaths

John Henry Hale, Nashville, Tenn.; Meharry Medical College, Nashville, 1905; professor and chairman of the department of surgery at his alma mater, where he had been associate director of the tumor clinic; past president of the National Medical Association; served as medical director of the health department at the Tennessee State College; at one time surgeon in chief at the Millie E. Hale Hospital; was to have been awarded a Distinguished Service Medal this month at the John A. Andrew Clinic at Tuskegee Institute, Ala., for outstanding contributions to the Negro medical profession; chairman of the hospital committee and chief, surgical department, George W. Hubbard Hospital of Meharry Medical College, where he died March 27, aged 62, of myocardial insufficiency.

Arnold Schwyzer • St. Paul; Universität Zürich Medizinische Fakultät, Switzerland, 1888; member of the founders group of the American Board of Surgery; professorial lecturer emeritus at the University of Minnesota Medical School, Minneapolis; formerly professor of clinical surgery at the Minneapolis College of Physicians and Surgeons, the Medical Department of Hamline University; member of the Minnesota Pathological Society, Minnesota Academy of Medicine, Swiss Surgical Society, American Surgical Association and the Western Surgical Association; fellow of the American College of Surgeons; for many years surgeon on the staff of St. Joseph's Hospital; died February 19, aged 79, of carcinoma of the pancreas.

Peter Lyons Harvie • Troy, N. Y.; Harvard Medical School, Boston, 1911; a member of the founders group of the American Board of Surgery; formerly instructor in surgery at the Albany Medical College, Albany; fellow of the American College of Surgeons; served in the medical corps of the U. S. Army on the Mexican border and as a captain, commanding ambulance company number 5, third division, American Expeditionary Forces, in France during World War I; surgeon, Samaritan Hospital, Eddy Memorial Foundation and Day Home Clinic; thoracic surgeon, Pawling Sanatorium, Wyncottskill; consulting surgeon, Henry W. Putnam Memorial Hospital, Bennington, Vt.; died February 4, aged 58, of heart disease.

Cyril Sumner • Rochester, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1911; served as consultant in general surgery and instructor in surgery at the University of Rochester School of Medicine and Dentistry; past president of the Rochester Academy of Medicine; member of the founders group of the American Board of Surgery; fellow of the American College of Surgeons; served during World War I; director of the surgical department, Genesee Hospital; attending surgeon, Monroe County Hospital; for many years on the staff of the Strong Memorial Hospital; died February 7, aged 61, of diverticulitis.

Louis Provance McCormick • Connellsville, Pa.; Jefferson Medical College of Philadelphia, 1891; retired from the Pennsylvania National Guard in 1915 with the rank of lieutenant colonel after twenty-one years of service; served during the Spanish-American War and the Philippine Insurrection; chairman of the Fayette County Draft Board number 2 during World War I and the Fayette County Selective Service Board number 1 during World War II; on the staff of the Connellsville State Hospital; treasurer, board of directors, Carnegie Free Library, and director of the Second National Bank; died February 6, aged 77, of angina pectoris.

Robert J. Walker • Saugatuck, Mich.; Trinity Medical College, Toronto, Ont., Canada, 1895; past president of the Allegan County Medical Society and the Ottawa County Medical Society; first lieutenant in the medical corps of the U. S. Army during World War I, serving as commanding officer of a hospital train; at one time village health officer and member of the school board; on the staff of the Allegan Health Center, Allegan, and formerly on the staff of the Community Hospital, Douglas; for many years a director and president of the Fruit Growers State Bank; died February 1, aged 74, of lymphatic leukemia.

Raymond Welsh Holt • Niagara Falls, N. Y.; University of Buffalo School of Medicine, 1928; specialist certified by the American Board of Pediatrics, Inc.; member of the American Academy of Pediatrics; served overseas with the American Expeditionary Forces during World War I; attending pediatrician, Mount St. Mary's and Niagara Falls Memorial hospitals; formerly on the staff of the Children's Hospital,

Buffalo; director, board of Beaman Foundation Child Guidance Clinic; member of the Rotary Club; died in the Buffalo General Hospital, Buffalo, February 4, aged 50, following an operation.

Fred Meade Anderson, Nickerson, Kan.; St. Louis University School of Medicine, 1904; member of the Kansas Medical Society; died in St. Elizabeth Mercy Hospital, Hutchinson, January 17, aged 64, of cerebral hemorrhage.

John Ashburton Cutter, New York; Albany Medical College, New York, 1886; joint author of "Food: Its Relation to Health and Disease"; died in St. Vincent's Hospital February 13, aged 80, of arteriosclerotic heart disease, cerebral arteriosclerosis and bronchopneumonia.

George Bernard Grady, Watervliet, N. Y.; Albany Medical College, 1896; at one time a druggist; for many years medical supervisor of the schools and police surgeon; served as health officer; on the staff of the Troy Hospital, Troy; died February 15, aged 73, of heart disease.

Henry Hill Haskell, Carmel, Calif.; Harvard Medical School, Boston, 1893; served as assistant in ophthalmology at his alma mater; formerly a member of the American Ophthalmological Society and the New England Ophthalmological Society; for many years on the staff of the Massachusetts Charitable Eye and Ear Infirmary, Boston; died February 14, aged 75, of pulmonary edema and acute dilatation of the heart.

William Ellery Hughes • Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1880; at one time professor of clinical medicine at the Medico-Chirurgical College of Philadelphia; consulting physician to the Philadelphia General, Misericordia and Presbyterian hospitals; accompanied Admiral Robert E. Peary on one of his early polar expeditions; died March 16, aged 87, of arteriosclerotic cardiopathy.

Sidney Hughes Jacobs, Atlanta, Ga.; Atlanta College of Physicians and Surgeons, 1910; formerly passed assistant surgeon in the U. S. Public Health Service reserve; served during World War I; died February 15, aged 60, of coronary thrombosis.

Sherman Willott Jenkins, Detroit; Meharry Medical College, Nashville, Tenn., 1926; on the staffs of the Wayne Diagnostic and Parkside hospitals; died in Jackson, Mich., February 20, aged 47, of coronary occlusion.

Christopher George Johnson • Milwaukee; Trinity Medical College, Toronto, Ont., Canada, 1895; died February 18, aged 73, of myelogenous leukemia.

John Frank Johnson, Chicago; Jenner Medical College, Chicago, 1903; died February 19, aged 72, of chronic myocarditis.

Edward Charles Jones • Montclair, N. J.; Tufts College Medical School, Boston, 1927; member of the American Society of Anesthetists, Inc.; on the staffs of the Mountainside, Community and St. Vincent's hospitals, Montclair, and the Essex County Hospital for Contagious Diseases, Belleville; died February 16, aged 52, of congestive heart disease.

Henry Turner Kendall, Columbia, S. C.; Hospital College of Medicine, Louisville, Ky., 1889; died in the Columbia Hospital February 21, aged 83, of pneumonia.

Herbert L. Lake, Lyons, N. Y.; Eclectic Medical Institute, Cincinnati, 1882; died January 30, aged 83, of chronic nephritis and arteriosclerotic heart disease.

Charles C. Landon, Battle Creek, Mich.; the Hahnemann Medical College and Hospital, Chicago, 1885; member of the Michigan State Medical Society; on the staffs of the Leila Y. Post Montgomery and the Community hospitals; formerly a member of the board of education and president of the Y. M. C. A.; died February 7, aged 84, of diabetes mellitus.

Charles Edwin Legg • South Sioux City, Neb.; Kansas City (Mo.) Hahnemann Medical College, 1904; served in France during World War I; on the staff of the Methodist Hospital, Sioux City, Iowa; surgeon for the Burlington Railway; died February 15, aged 68, of coronary occlusion.

Theophilus H. Littell, Ville Platte, La.; Medical Department of Tulane University of Louisiana, New Orleans, 1898; for many years coroner of Evangeline parish; died February 11, aged 69, of coronary thrombosis and cardiac insufficiency.

David Livingstone • Centralia, Wash.; Trinity Medical College, Toronto, Ont., Canada, 1904; served during World War I; captain in the medical reserve corps of the U. S. Army, not on active duty; formerly medical superintendent of the Western State Hospital, Fort Steilacoom; died February 15, aged 65, of hypostatic pneumonia following influenza.

James C. MacGregor, Flint, Mich.; Detroit College of Medicine, 1898; also a pharmacist; member of the Michigan State Medical Society; past president of the Genesee County Medical Society; member of the board of managers of the Hurley Hospital for many years; served on the board of directors of the Industrial Savings Bank, the Union Industrial Trust and Savings Bank and the National Bank of Flint; died February 29, aged 72, of cardiac thrombosis.

Finley Joseph McRae * Albion, Neb.; Western University Faculty of Medicine, London, Ont., Canada, 1902; secretary of the Boone County Medical Society; served as a captain in the medical corps of the U. S. Army during World War I; a director of the Nebraska Tuberculosis Association; past president of the Kiwanis Club; died in Our Lady of Lourdes Hospital, Norfolk, January 5, aged 67, of cerebral hemorrhage.

Hovsep Hagop Mahdesian, Fresno, Calif.; American University of Beirut School of Medicine, Syria, 1908; died in St. Agnes Hospital February 3, aged 60, of complications due to a duodenal ulcer.

Jacob Earl Meengs * Grand Rapids, Mich.; Rush Medical College, Chicago, 1904; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; died February 2, aged 62, of valvular heart disease, arteriosclerosis and general edema with pleuritic effusion on the right side.

Charles A. Moore, Tampa, Fla.; Eclectic Medical Institute, Cincinnati, 1885; died in the Tampa Municipal Hospital February 6, aged 84, of cerebral hemorrhage.

Louis Grant Morrill, St. Clair, Mich.; Northwestern University Medical School, Chicago, 1913; member of the Michigan State Medical Society; formerly clinical assistant, instructor and associate in surgery at his alma mater; for many years on the staff of St. Luke's Hospital, Chicago, and had also been connected with the Commonwealth Edison Company in Chicago; died in the University Hospital, Ann Arbor, February 1, aged 65, of cerebral hemorrhage.

Solomon B. Myers, Mount Holly Springs, Pa.; Chicago Homeopathic Medical College, 1887; on the courtesy staff of the Carlisle Hospital, Carlisle, where he died February 1, aged 89, of myocardosis due to arteriosclerosis.

Henry Joseph Noerling * Valatie, N. Y.; Albany Medical College, 1911; mayor of the village of Valatie; president of the Columbia County Board of Health and the Valatie Savings and Loan Association; member of the board of trustees of the National Union Bank of Kinderhook; on the staffs of the Hudson City Hospital, Hudson, and the Albany Hospital, Albany; died February 4, aged 55, of hypertension and myocardial degeneration.

George Henry Palmerlee, Detroit; Detroit College of Medicine, 1903; member of the Michigan State Medical Society; fellow of the American College of Surgeons; veteran of the Spanish-American War; served as a major in the National Guard; formerly medical inspector of the city board of health; on the staff of the Grace Hospital, where he died January 22, aged 71, of coronary thrombosis.

Don V. Poindexter, East St. Louis, Ill.; Marion-Sims College of Medicine, St. Louis, 1898; served one term as coroner of Bond County; died in St. Mary's Hospital, January 9, aged 69, of myocarditis and bronchiectasis.

Walter S. Quaintance, Slate Mills, Va.; University College of Medicine, Richmond, 1904; also a dentist; died in the University of Virginia Hospital, University, February 3, aged 62, of coronary thrombosis.

James Thomas Rainer * Yazoo City, Miss.; Memphis (Tenn.) Hospital Medical College, 1912; member of the Mississippi State Medical Association; county physician; served overseas during World War I; on the staffs of King's Daughters Hospital and the Yazoo Clinic and Hospital; died February 3, aged 54, of cardiovascular renal disease.

Walter R. Schmidt, Glencoe, Minn.; University of Minnesota College of Medicine and Surgery, Minneapolis, 1903; member of the Minnesota State Medical Association; served as coroner and health officer; clerk of school board at Chisholm; on the staff of Glencoe Municipal Hospital; died January 20, aged 65, of carcinoma with metastasis in the left axilla.

Samuel S. Shorer, Milwaukee; Bennett College of Eclectic Medicine and Surgery, Chicago, 1885; died January 5, aged 81, of influenza, acute bronchitis, arteriosclerosis and cardiorenal disease.

Edward Sylvester Smith, Bridgeport, Conn.; New York Homeopathic Medical College and Hospital, New York, 1888; served as president of the board of directors of the Y. M.

C. A.; died in the Dr. J. H. Evans' Private Hospital, New Haven, February 4, aged 86, of arteriosclerotic heart disease and chronic arthritis.

William Thomas Stewart, Oxford, Ohio; Medical College of Ohio, Cincinnati, 1908; member of the Ohio State Medical Association; served in France as a captain in the medical corps of the U. S. Army during World War I; past president of the Butler County Board of Health; on the staffs of the Fort Hamilton Hospital and the Mercy Hospital, Hamilton, where he died January 23, aged 65, of Paget's disease and uremia.

Charles Midwood Stiles, Philadelphia; Medico-Chirurgical College of Philadelphia, 1898; member of the Medical Society of the State of Pennsylvania and the American Academy of Ophthalmology and Otolaryngology; served as a captain in the medical corps of the U. S. Army during World War I; for many years on the staff of the Frankford Hospital; died in the Veterans Administration Facility, Coatesville, January 27, aged 77, of bronchopneumonia.

James Milton Still, Dallas, Texas; Marion-Sims College of Medicine, St. Louis, 1892; past president of the Kaufman County Medical Society; at one time health officer of Kaufman County; died January 27, aged 74, of carcinoma of the buccal cavity.

Benjamin Early Stockwell * St. Louis; Barnes Medical College, St. Louis, 1904; died February 2, aged 80, of heart disease.

William Veazey, Van Alstyne, Texas; University of Louisville (Ky.) Medical Department, 1898; for many years a member of the local school board; died in San Antonio January 27, aged 69, of cerebral arteriosclerosis.

Levin West * Frederick, Md.; University of Maryland School of Medicine, Baltimore, 1886; served on the staffs of the Schnauffer Hospital, Brunswick, and the Frederick City Hospital; died January 30, aged 79, of cerebral embolism.

Clarence John Wichser, New Orleans; Tulane University of Louisiana School of Medicine, New Orleans, 1920; member of the Louisiana State Medical Society; physician in chief, city sewerage and water board; died in the Mercy Hospital January 25, aged 52, of cardiac infarct.

DIED WHILE IN MILITARY SERVICE

Frank Bolles Wakeman * Colonel, M. C., U. S. Army, Washington, D. C.; Indiana University School of Medicine, Indianapolis, 1926; graduated in pharmacy, Valparaiso University in 1915, received degree in pharmaceutical chemistry, 1916, and the degree of bachelor of science, 1917; served in World War I from August 1917 to May 31, 1919, as a first lieutenant, infantry, Officers Reserve Corps; overseas with the 369th U. S. Infantry (old fifteenth New York Infantry); on active duty as a first lieutenant, medical reserve corps from Aug. 1, 1926 to Aug. 21, 1927, during which time he completed an internship at Walter Reed General Hospital; practiced medicine in Indiana from August 1927 to May 1928; appointed as a first lieutenant in the medical corps, regular army, on March 23, 1928; promoted to captain on June 3, 1928, major, June 4, 1937, temporary lieutenant colonel on Feb. 1, 1942 and temporary colonel on Sept. 8, 1942; graduate from basic course, Army Medical School, 1929, and advanced course, 1936; graduate from basic course, Medical Field Service School, Carlisle Barracks, 1929, and advanced course, 1938; served as an instructor in biochemistry at Army Medical School, 1932-1936, and instructor in sanitation at Medical Field Service School, 1937-1939; received the degree of master of arts in 1933 and the degree of doctor of philosophy in 1935 from Catholic University of America and the degree of doctor of public health in 1937 from Johns Hopkins University School of Public Health; graduated from the Command and General Staff School, Fort Leavenworth, Kan., in 1940; awarded the Henry Wellcome prize in 1938 by the Association of Military Surgeons of the United States for his essay on "A Specific Somatic Polysaccharide as the Essential Immunizing Antigen of the Typhoid Bacillus"; chief of the Training Division, Office of the Surgeon General, since February 1940; member of the Association of Military Surgeons of the United States and the Society of American Bacteriologists; fellow of the American College of Physicians; died in Fort Monmouth, N. J., March 17, aged 47, of coronary occlusion, while attending a conference of G-3 officers.

Correspondence

THE HISTORY OF PENICILLIN

To the Editor:—It is not too early to take considerable care in recounting the history of the development of penicillin. The remarkably rapid increase of professional as well as public interest in this potent but nontoxic bactericide dictates such caution. The full story of its rediscovery by Florey, Chain and their co-workers nine years after its original discovery by Fleming in 1929 has not yet been fully recorded. This is probably largely because Professor Florey has not wanted to detract from the honor due Prof. Alexander Fleming, its original discoverer, who is still living and still a brilliant observer. This is only just, but the lack of a full account of its rediscovery can lead to mistaken notions. Thus Herrell writes in *THE JOURNAL*, March 4, "Following the isolation of an antibacterial agent, gramicidin, from *Bacillus brevis* by Dubos in 1939, a reinvestigation of substances of biologic origin was naturally undertaken. Chain and other Oxford investigators in 1940 reported on penicillin and its possibilities as a chemotherapeutic agent." This statement appears to suggest that the rediscovery of penicillin at Oxford was stimulated by the development of gramicidin. This was not the case. Actually it was work on a less well known antibacterial agent, lysozyme, that had most to do with creating interest in penicillin at the Sir William Dunn Institute of Pathology.

Lysozyme, which also was discovered by Fleming, is a potent antibacterial enzyme found in most body tissues. It occurs in high concentration in human tears, in human saliva and particularly in egg-white. Egg-white lysozyme has been crystallized and found to be a carbohydrate-splitting enzyme. Before the development of gramicidin it was perhaps the best known of all the antibacterials of cellular origin. Florey had been interested in it for some time and had published on it as early as 1930.

In the fall of 1937 I came to Oxford as a Rhodes scholar to work in Florey's laboratory. He assigned me my doctorate thesis subject, "The Actions of Certain Bacteriolytic Principles," allowed me to choose Dr. Ernest Chain, a brilliant biochemist, as my supervisor, and bade me get to work to isolate the substrate of lysozyme. We did succeed in doing this, confirming and extending the findings of Karl Meyer and his co-workers. During the course of this work we began to share Florey's interest in other antibacterials of cellular origin, such as pyocyanin, actinomycin, streptothricin and bacteriophage. We read Fleming's original 1929 paper on penicillin, were most impressed with the possibilities of the subject and found it difficult to understand why the study of penicillin had practically lapsed for nine years. It appeared that this was probably due mainly to the difficulties in purification of the substance and not because the observations had not been confirmed.

We were very fortunate in being able to borrow a strain of the Fleming *Penicillium notatum* from another research investigator in the Sir William Dunn School of Pathology, Miss Campbell-Renton. She had kept the original Fleming strain going, hoping to work on penicillin sometime when her bacteriophage studies with Prof. A. D. Gardner did not claim all her time. With Florey's permission, Chain and I recultured this strain and tested the antibacterial properties of the medium on several cocci. The results were not impressive. Preliminary experiments rarely are. It was a particularly busy moment in the lysozyme research, so Professor Florey asked Dr. Norman Heatley to work with Chain on the further development of penicillin. This was in 1938, as I recall. Heatley and Chain, with the active advice of Professor Florey, succeeded in purifying and standardizing penicillin, and by the late spring of 1940 hard work had produced enough partially

purified penicillin for use in animal experiments. These experiments were well planned and were immediately and brilliantly successful. Classically dramatic results were obtained. The importance of the findings was understood at once, and practically the whole Sir William Dunn Institute of Pathology was turned over to penicillin research, the work being financed mainly by the British Medical Research Council. It is a tribute to the wisdom of British science and to the British people as a whole that all this was accomplished at exactly the period of the greatest peril to their country—when France capitulated and when it appeared possible that the Nazis would invade England itself. The development of the clinical use of penicillin grew rapidly, and Professor Florey's visit to the United States in the summer of 1941 stimulated interest in it here. Commercial production was undertaken, with what results is now well known. It has been wisely shepherded by the National Research Council and given only to qualified investigators.

As will be obvious from the preceding account, my contact with the development of penicillin was largely tangential, although I did have the opportunity to work with it again under Prof. Warfield T. Longcope and Dr. Murray Fisher during my internship at the Johns Hopkins Hospital. It has been possible for me to observe, however, various steps in its development. That is why I am impelled to enumerate a few facts about its development at Oxford.

LESLIE A. FALK, 1st Lieutenant, M. C., A. U. S.

TOXICITY OF SODIUM BENZOATE

To the Editor:—With the increasing use of the synthesis of hippuric acid as a test of liver function, the toxicity of sodium benzoate requires careful reevaluation. Recently Kinsey and Wright (*J. Lab. & Clin. Med.* 29:188 [Feb.] 1944) reported that, after a patient recovering from a serious attack of hepatitis had taken the usual dose of 6 Gm. of sodium benzoate as used in the test, a strong reaction ensued: severe substernal pain, shock, increased icterus and later granulocytopenia and eosinophilia. To my knowledge this is the first severe reaction from sodium benzoate reported in the literature, although I have been informed of several cases in which untoward reactions to this drug were shown.

Sodium benzoate, generally speaking, is one of the most innocuous drugs known. Some of the older clinicians, Senator, for instance, gave doses of 12 Gm. daily to their rheumatic patients. Several investigators reported taking 40 Gm. or more of sodium benzoate in twenty-four hours with no pronounced toxic effect. I, as well as many others, have performed the hippuric acid test on patients with severe acute hepatitis without any demonstrable reaction.

In view of these observations, it seems clear that sodium benzoate has little or no direct toxic action other than occasionally causing nausea. When, therefore, a severe reaction occurs, a hypersensitivity has in all probability developed. Since benzoic acid lacks reactive groups in the ring, it is unlikely that it per se acts as a hapten. Since only about 80 per cent of the ingested benzoic acid is recovered as hippuric acid, it seems fairly certain that some of the compound is metabolized, and it is probable that a metabolic product, perhaps a hydroxybenzoic acid or a phenol, may be the factor to which the organism has become hypersensitive. This appears all the more likely in view of the fact that the patient of Kinsey and Wright had his toxic reaction not immediately but four hours after the sodium benzoate had been given. Since considerable benzoic acid is taken into the body almost daily in the food either as such or as quinic acid, which is converted to benzoic acid, sensitivity to benzoic acid must be exceedingly rare. It therefore seems justifiable to state that the danger of a serious reaction from sodium benzoate is so remote that one need not hesitate to do the oral hippuric

acid test whenever the information that this test supplies is deemed desirable.

The intravenous modification has been used extensively in various clinics and hospitals for the past few years. The incidence of untoward reactions is somewhat higher, but except for a few isolated instances the reactions have been transient. It is likely that many of these reactions are on a psychic basis brought on by the fact that the injection requires about five minutes, and that a cramplike pain may be produced if the solution is administered too fast. It should be emphasized that only a properly prepared solution of sodium benzoate be injected. Unless one has all the facilities to make solutions safe for intravenous administration, it is advisable to use commercial ampules prepared for the test.

While toxic reactions from sodium benzoate are rare, it is nevertheless important to know that they can occur, since forewarned is forearmed. The desirability of reporting toxic effects from sodium benzoate as well as from other drugs cannot be overstressed, since this is the only means whereby the relative safety of any drug can be accurately evaluated.

ARMAND J. QUICK, M.D., Milwaukee.

LATE MUSCLE ATROPHY IN POLIOMYELITIS

To the Editor:—In the issue of March 4, page 676, the answer to a query on the relationship of poliomyelitis to late muscle atrophy denies any possible correlation between the two conditions and states that the latter condition would be due "to some new injury to or disease of the muscle or its corresponding nerve." However, a number of cases of chronic anterior horn cell atrophy of a noninflammatory nature (progressive muscular atrophy, progressive nuclear atrophy) have been described, which have followed after a variable interval an attack of poliomyelitis. This degenerative condition has usually been reported in persons who have exercised their muscles strenuously; in a mountain climber, for example, and I saw it appear in a ditch digger two years after a typical attack of poliomyelitis. Thus it does seem that in some individuals the original inflammatory lesion of poliomyelitis leaves a locus of least resistance, which later succumbs to a degenerative process, of which the results seem identical with those ordinarily described in progressive muscular atrophy. Pronounced muscular activity seems to play some role in the initiation of this atrophy.

LEO A. SPIEGEL, M.D., New York.

"IMMEDIATE CARE OF THE NEWBORN"

To the Editor:—This communication is in reference to the article on "Immediate Care of the Newborn in Relation to Neonatal Mortality," by Ralph M. Tyson, M.D., which appeared in THE JOURNAL, February 5.

In the section on skin infections he recommends that a 5 per cent lotion of sulfathiazole be applied freely. "Exposure to ultraviolet radiation at a close distance is helpful." Many dermatologists are seeing eruptions following the external use of sulfonamides in various vehicles. Many of us believe that their use is being overdone. This applies particularly to impetigo, in which ammoniated mercury is still preferred.

The sulfonamides are apt to produce sensitization just as much as and more so than ammoniated mercury. The sulfonamide compounds also sensitize the skin to the sun and I strongly advise against the concurrent use of ultraviolet rays that the author suggests—not only in impetigo but also in the treatment of any other disease. An article of mine in preparation cites the deleterious effects of ultraviolet rays applied to the skin after the topical application of sulfonamide ointment.

E. WILLIAM ABRAMOWITZ, M.D., New York.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: *Oral and Written. Part I*. Chicago, New Orleans, New York and San Francisco, October. Final date for filing application is August 1. Sec., Dr. G. A. Caldwell, 3503 Prytania St., New Orleans.

AMERICAN BOARD OF OTOLARYNGOLOGY: *Oral*. New York City, June 1-4. Sec., Dr. Dean M. Lierle, University Hospitals, Iowa City, Ia.

AMERICAN BOARD OF PATHOLOGY: *Oral and Written*. Chicago, June 7-8. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit.

AMERICAN BOARD OF PEDIATRICS: *Written*. Locally, Sept. 22. *Oral*. St. Louis, Nov. 8-9. Final date for filing application is Aug. 15. Sec., Dr. C. A. Aldrich, 115½ First Ave. S.W., Rochester, Minn.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Compensation of Physicians: Reasonableness of Fee for Mastoidectomy.—The physician plaintiff, an otologist, on June 19, 1937 performed a mastoidectomy on the patient for an infection involving the petrous portion. Beginning about six months later the physician made more than sixty visits to the patient, for what purpose the reported case is not clear but "not in connection with postoperative treatment." When the operation was performed the patient was a minor and arrangements for it were made by his uncle, who was told by the physician that the charge for the operation would be very moderate. In March 1938 the patient was emancipated by court judgment and subsequently inherited approximately \$40,000 from the estate of his father. Apparently unaware of the inheritance, the physician billed the patient for \$400 for the operation and \$115 for subsequent visits. Between April 1939 and January 1940 the patient paid the physician a total of \$80 on account and sent him letters in which he expressed appreciation for the consideration shown him, admitted the bill was fair, and stated his intention to pay as soon as he could. Subsequently the physician sued the patient for the unpaid balance. The patient defended by claiming that the amount charged for the operation was excessive and that the sixty or more professional visits for which charges had been made "were made necessary because of postoperative treatment" for which no additional charges should have been made. From a judgment, in the main, for the physician the patient appealed to the court of appeal of Louisiana, Orleans Parish.

The appellate court held that the amount charged for the operation was not excessive in view of the testimony of two "recognized otologists," called as witnesses by the physician at the trial, to the effect that the performance of a mastoidectomy "for a petrous infection" was most serious and that a charge of \$400 for such an operation would be the minimum which should be charged. Even though the physician, said the court, may have told the patient's uncle that the charge would be very moderate, surely the physician did not intend to give the impression that he would make no charge at all but merely that he would make the minimum charge usual for such an operation. In determining what is a correct charge for professional services, there should be considered two things: first, the training and experience necessary and the seriousness of the treatment or operation; and, second, the ability of the defendant to pay. We do not mean that because a defendant may be a very rich man he may be required to pay an exorbitant charge, but we do mean that, where a defendant is shown to be well able to pay, the physician should not be required to reduce his charge and in fixing it may take into consideration the fact that the patient has ample funds out of which to make the payment.

At the trial, to prove the reasonableness of the charge made for the operation, the physician called the two otologists referred to, who heard all of the evidence at the trial. At the close of the evidence, counsel for the plaintiff asked for a rule on the defendant to tax the witness fees of these two otologists as costs of court and asked that those fees be fixed at \$50 each. Counsel for the defendant contended that these charges should not be taxed as costs of court first, because the testimony was not expert evidence and, secondly, because in support of the rule to tax their fees the two experts themselves did not take the witness stand but merely submitted bills to the court. The patient contended that the testimony of the otologists was not expert testimony because no special study or experience in any branch of science was necessary to give the testimony they gave. The patient called attention to a Louisiana statute which provides that witness fees, in addition to the fees allowable to an ordinary witness, may be allowed by the court with respect to a witness called to testify only to an opinion founded on special study or experience in any branch of science (Dart's Revised Statutes, vol. 1, sec. 1990). The patient argued that any layman who had employed a physician may testify as to what the charge made against him was and from such experience might testify as to what such charges should be. We cannot agree with this contention, said the appellate court. It is true that any layman who has required the services of a physician may know what charge was made against him and it is true that any layman who has required such services often may have acquired experience which will enable him to judge, with fair accuracy, just what charge will be made for any given services. However, only one who has himself had experience in rendering the same kind of service or in performing the same kind of operation or who has had experience in making charges therefor may be said to be capable of giving expert testimony on the subject. Where the bill of a physician is questioned, the best evidence as to its correctness must be given by another physician who has himself studied the same branch of science and knows how serious may have been the condition of the patient, or how dangerous may have been the operation. The court accordingly concluded that the two otologists gave expert testimony and that therefor their fees as experts should be taxed as costs of court if properly proved. The court, however, held that their fees were not properly proved since they did not take the witness stand and thus submit themselves to cross examination but only submitted bills to the court. The court held that the witness fees of the otologists could not be allowed at this time.

The judgment in favor of the physician for the unpaid balance of his charges for the operation and the subsequent visits was affirmed.—*Womack v. Burke*, 14 So. (2d) 302 (La., 1943).

- West Virginia Medical Association, Wheeling, May 15-16 Mr. Charles Lively, P. O. Box 1031, Charleston, Executive Secretary.

Current Medical Literature**AMERICAN**

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1934 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Yellow Fever and Typhus: Possibility of Their Introduction into the United States.—Sawyer shows that the most serious risk of introducing yellow fever is through air travel. Travelers visiting infected regions have been encouraged to get themselves vaccinated. Passengers arriving from endemic areas are inspected by quarantine officers. Persons showing elevation of temperature or other evidence of illness are detained until a diagnosis is made. Those who are well and are nonimmune but who have possibly been exposed within a few days are kept under surveillance for the remainder of the incubation period of six days unless the destination is north of any region in which *Aedes aegypti* might breed. The control of *Aedes aegypti* remains the method of choice for cities and other places in the tropics and subtropics where this mosquito has become established. *Aedes aegypti* is especially vulnerable, as it is highly domestic and accessible and not so widely distributed as is commonly supposed. This makes it possible for health departments to organize a systematic attack on the mosquito in its larval stages and so hasten this dangerous insect on the way to local extermination. Most effective methods have been worked out in Brazil and applied with such success that in most cities and in many large areas *Aedes aegypti* can no longer be found. Introduction of louse borne typhus by returning troops would seem improbable. There are, however, other ways in which louse borne typhus can enter this country in time of war and spread as far as the local louse infestation will permit. The point is illustrated by the occurrence observed in the Southwest in 1916. The present situation in the United States with respect to the risks of typhus introduction is quite different from the one in 1916.

All that protected us from a widespread epidemic of typhus during the last war was the general freedom of the public from body lice. As a rule the disease showed no tendency to spread beyond the immediate contacts of the persons introducing it into the communities. There is no reason to believe that lousiness is any more prevalent now than then or that war conditions will bring about a great increase in these insects.

Tropical and Imported Malaria.—McCoy emphasizes that large numbers of troops returned from overseas are infected with malaria. Although there is a hazard of the establishment of new foci of malaria infections of the country now free of the disease, the chances of serious consequences from such introduction are not considered very great. Prompt antimosquito measures should bring about rapid control of possible outbreaks. Intensification of anopheline mosquito control is indicated in the present endemic areas in this country to lessen the hazard from the introduction of new strains of malarial parasites. The most important problem connected with the return of military personnel infected with malaria is to insure proper diagnosis and treatment of the relapses which may occur after the service men have returned to their home communities.

Immunizations in the United States Army.—Long discusses the prevention of disease by immunization procedures. These immunizations have been divided into two classifications: the so-called routine immunizations and the special immunizations. The routine immunizations are those administered to all military personnel as soon as possible after entrance into the federal service. These are vaccinations against smallpox, typhoid and the paratyphoid fevers and active immunization against tetanus. Procedures referred to as special immunizations include vaccination against yellow fever, typhus and cholera. Vaccination against plague is another procedure for which provisions have been made. As in typhus and cholera, sanitary measures are stressed for the prevention of plague, and it is believed that in the majority of instances these measures will prove to be adequate protection. Plague vaccine is not now routinely administered to troops but is supplied to forces in areas where danger from the disease may be confronted. Immunization against such diseases as diphtheria and scarlet fever is not routinely practiced, but materials are made available for use if the situation should require artificial protection against these diseases.

 Three and One-Half Years' Experience with the 1,000 Kilovolt Roentgen Therapy Unit at Memorial Hospital. A. F. Hocker and Ruth J. Gutman.—p. 83.

Nontuberculous Pulmonary Cavitation.—Nathanson and Morgenstern illustrate roentgenographically lesions of the lung which presented cavitation or what simulated cavitation, particularly of the upper lobes, and which on biopsy or necropsy proved to be nontuberculous. The majority of these patients were referred to Sea View Hospital from other metropolitan hospitals with the diagnosis of tuberculosis made clinically, roentgenographically and in 1 instance apparently by a positive sputum examination. The authors present 8 cases with anthracosis, cystic disease of the lung, actinomycosis, aortic aneurysm producing pulmonary necrosis, bronchogenic neoplasm with parenchymal necrosis, a lung abscess of the upper lobe, cavitation probably as a result of Friedländer's bacillus infection

of the lung, and a case of bronchiectatic cavitation of the upper lobe. Other lesions will produce cavitation in the lung, and Winn has recently reported 12 cases of pulmonary cavitation associated with coccidioid infection. Slowly resolving non-specific pneumonias may present areas of clearing that simulate cavitation, and one may find cysts or bleb formation in association with pneumonias in children which will suggest a tuberculous lesion. Occasionally a gumma may cavitate centrally and simulate tuberculosis. The authors stress that roentgenographic demonstration of cavitation is not conclusive for the diagnosis of pulmonary lesions and that the possibility of other pulmonary lesions must be kept in mind.

Emphysematous Cholecystitis.—Stevenson defines emphysematous cholecystitis as an acute infection of the gallbladder characterized by gas production in the gallbladder lumen, walls and pericholecystic tissues. Any virulent gas-producing organism may be responsible. Hegner in 1931 reported what apparently was the first case in which it was possible to make a preoperative diagnosis of this condition by means of roentgenography. Stevenson's 3 patients had roentgenologic aspects similar to Hegner's patient. All 3 were men, aged 64, 63 and 52 respectively. All 3 patients showed gas in the gallbladder, blebs in the wall and collections of gas in the pericholecystic tissues. No gas was noted within the biliary duct system. In 2 of the patients the condition was correctly diagnosed preoperatively. Medical treatment consisting of sulfathiazole, Clostridium welchii antiserum and roentgen radiation was successful in the treatment of 1 case. The author concludes that roentgenograms of the gallbladder region are of distinct value in cases of acute cholecystitis. The roentgenographic demonstration of gas in the gallbladder lumen, emphysematous blebs in the gallbladder wall and collections of gas in the pericholecystic tissues is indicative of acute gangrenous cholecystitis, most likely caused by *Cl. welchii*.

Silicotuberculosis.—To determine whether pneumoconiosis alters or is itself altered by pulmonary tuberculosis, Auerbach and Stemmerman reviewed 54 cases of silicotuberculosis and compared them with 9 cases of pneumoconiosis without tuberculosis and 200 cases of tuberculosis without pneumoconiosis. They found that, although silicosis and tuberculosis exist concomitantly in the same lung, each maintains its individual integrity. Tuberculosis apparently does not alter the silicosis present. Pneumoconiosis alters tuberculosis only to the extent that the silicotic nodules prevent the full development of tuberculous granulation tissue and, in the walls of cavities, the pyogenic membrane. Both granulation tissue and pyogenic membrane, however, are present in those portions of the lung where the silicotic foci are small or absent. Except for this quantitative difference they found little variation in the tuberculous process, whether or not pneumoconiosis is present. The size, situation and number of cavities are approximately the same. There is a slightly greater incidence of perforation of cavities through the interlobar fissures in the silicotic and a greater incidence of death from fatal pulmonary hemorrhage. The latter factor is due to the greater productive reaction in the silicotic lung with greater opportunity to develop an aneurysm of a branch of the pulmonary artery. The authors found it difficult to determine the exact time at which pulmonary tuberculosis was superimposed on pneumoconiosis unless the patient was under observation during the transition period, since the symptoms of the two diseases are similar. While fever and definite evidence of cavitation on roentgenography are useful diagnostic aids, the final conclusion must

be based on the demonstration of the tubercle bacillus. Collapse therapy was of little value in cases of silicotuberculosis. This is apparently due to the fact that the silicotic lung remains voluminous and shows no tendency to collapse. Most patients succumbed to progressive pulmonary insufficiency. When the tuberculous process invaded the remaining portions of resilient lung tissue sufficiently, death was inevitable.

Influence of Respiration on Blood Pressure.—Battro and his associates studied the registration of the intra-arterial pressure of human subjects. They ascertained that under normal conditions two principal types of waves exist: (1) vasomotor waves, which are independent of the respiratory movements and should be called by the names of their discoverers, Traube and Hering, and (2) blood pressure waves depending on the respiratory movements (respiratory waves). The authors discuss the different factors which influence the production of these waves. The intra-arterial pressure has no uniform or fixed behavior during the respiratory movements but may rise or fall in accordance with the type of breathing—thoracic or abdominal—or with the frequency or depth of respiration. Even during ordinary breathing, slight changes are noticeable, the most constant being a fall of blood pressure during inspiration and an elevation during expiration. With deep, slow thoracic breathing there usually occur an inspiratory fall and an expiratory rise of the blood pressure. The opposite, as a rule, is true of abdominal breathing of the same type. Curves of intra-arterial pressure registered during inspiratory apnea and the Valsalva test show a definite fall of blood pressure at the beginning, while those taken during expiratory apnea are characterized by a slight initial fall and a terminal rise. Coughing causes great increase in the blood pressure.

Acetylcholine in Schizophrenia.—Cohen and his collaborators review the use of acetylcholine in the treatment of mental disease. Their studies were carried out on 11 patients. They describe a typical seizure that developed in 27 instances following the intravenous injection of 400 mg. of acetylcholine. A table lists age, duration of illness, number of treatments and

outcome in the 11 patients. The number of treatments varied between three and twenty-four. There was slight improvement in 1 woman, moderate improvement in another woman and remission in 1 man aged 36. The history of this last patient is described in detail. A total of twenty-four electric shock treatments had been ineffective. About five weeks after cessation of the electric treatments acetylcholine therapy was begun. Four treatments were given in all. The successive doses were 150, 300, 450 and 600 mg. The usual minor responses were noted during the first two treatments. He was pulseless for twenty seconds during the third treatment, with some twitching. During the fourth treatment he was several times pulseless for periods of from twenty to fifty seconds. After this therapeutic episode the dramatic remission took place. In 8 of 11 schizophrenic patients treated with convulsant doses of acetylcholine no general therapeutic benefit was obtained. The authors conclude that the therapeutic results do not justify the continued use of acetylcholine in this manner, particularly since the margin of safety of the drug appears to be extremely slight.

Dicoumarol in Trauma and Gangrene.—Brambel and Loker used dicoumarol and heparin in several cases. They treated (1) post-traumatic conditions with associated gangrene following crush injury, (2) diabetic and arteriosclerotic gangrene and (3) frostbite. Eleven cases are presented and analyzed. Without exception, all cases exhibited increased prothrombin activity, detectable in dilute plasma. This suggests an indication for the administration of hemorrhagic compounds to alter biochemical conditions favoring thrombus formation. The use of dicoumarol in the treatment of granulating and ulcerative lesions is not contraindicated if caution and adequate control are exercised. Emphasis is placed on the value of frequent determinations of the prothrombin clotting time as an index to dosage. No set dosage for dicoumarol was found in the cases presented. Some required much larger doses than others. No contraindications were found when sulfonamide compounds and the hemorrhagic agent (dicoumarol) were used concomitantly if average normal renal and hepatic functions were present. One patient was treated by amputation below the knee, since it was feared that he could not withstand the shock of midhigh amputation. This instance suggests that the midhigh amputation in a patient with arteriosclerotic and diabetic gangrene of the toes may be supplanted by amputation at a site of election below the knee if dicoumarol is administered. This thesis was supported in another patient, whose leg was amputated below the knee for diabetic gangrene of the toes.

Arthritis in an Army General Hospital.—Boland studied 350 cases of arthritis and allied conditions in the admissions to the medical service of an Army General Hospital. The cases were divided into those with peripheral joint complaints and those with symptoms referable to the back. The present discussion is limited to the first group, which comprised 61 per cent of the series. Approximately 19 per cent of the peripheral arthritides were of the rheumatoid type. Early joint effusion,

particularly in the knees, has been common. In 70 per cent of cases the joint involvement has been confined to the lower extremities alone. The metatarsophalangeal and interphalangeal joints of the toes were involved in 41 per cent of cases, while the corresponding joints in the fingers were affected in only 10 per cent. Such a distribution in rheumatoid arthritis is in sharp contrast to that encountered in the general population. Bacteriologic identification of the gonococcus and good clinical judgment are necessary before a diagnosis of gonorrheal arthritis can be made in the Army. If initial smears have failed to demonstrate the gonococcus, the diagnosis of gonorrheal arthritis has not been made. Osteoarthritis, gout and some of the rarer forms of arthritis have differed in no way from those seen in civilian practice. Psychogenic manifestations occur with appalling frequency in soldiers. Emotional upsets may bring about or intensify symptoms of pain, stiffness and limitation of motion in the joints and muscles. Twenty and six-tenths per cent of the cases with peripheral joint complaints were regarded as instances of psychogenic rheumatism, and 3.7 per cent of those with pathologic joint changes had a definite psychoneurotic coloring. Nineteen and one-tenth per cent of the group with backache were considered psychogenic and 26.5 per cent of those with roentgenographic or objective physical abnormalities of the back had a definite psychogenic overlay. In the vast majority of cases various psychoneurotic symptoms, such as anxiety, irritability, fatigue, insomnia and mental depressions, were present.

Pernicious Anemia Without Achlorhydria.—Askey shows that it is entirely contrary to the history of Addisonian pernicious anemia to occur in the presence of gastric secretion of free hydrochloric acid. The precise diagnosis of Addisonian pernicious anemia requires: 1. Elimination of the conditions other than Addisonian pernicious anemia which may cause a loss of intrinsic factor. 2. A biologic assay showing absence of intrinsic factor. 3. A response to desiccated hog stomach, which furnishes ultimately the specific anti-pernicious anemia liver principle, or to a highly purified liver fraction, such as the Dakin-West fraction. These postulates, although rigid, are mandatory if pernicious anemia is to be diagnosed in an individual with acid present. The diagnosis not infrequently has been made and later proved to be wrong. Reports of 47 cases of pernicious anemia without achlorhydria by other observers are reviewed by the author. He shows that none of these have been proved by complete precise criteria to be Addisonian pernicious anemia. It would seem wise to restrict the term pernicious anemia to the true or Addisonian pernicious anemia characterized by absolute anacidity, loss of intrinsic factor

and reduction of the specific liver principle. Until precise critical tests have proved that acid secretion can persist in pernicious anemia, the presence of acid in any case must be considered as ruling out addisonian pernicious anemia. The existence of true pernicious anemia without anacidity as yet cannot be accepted.

Idiopathic Hypoparathyroidism with Moniliasis.—Sutphin and his associates describe the histories of 5 patients in whom idiopathic hypoparathyroidism was accompanied by moniliasis. The first 3 of the patients were siblings. The authors discuss the association of moniliasis with hypoparathyroidism from four different points of view: (1) that there is no connection, (2) that hypoparathyroidism might be the result of moniliasis, (3) that moniliasis might result from hypoparathyroidism and (4) that both conditions might result from a third factor. They reach no definite conclusion but point out that the time relationships in the case histories suggest that the moniliasis precedes the hypoparathyroidism. Since the father and mother of patients 1, 2 and 3 were first cousins, and since all 3 patients, the father and other siblings had congenital hypochromic polycythemia, the possibility exists that the susceptibilities to monilia infection and to hypoparathyroidism are both connected with some defect in the germ plasm. The nail changes resulting from moniliasis did not improve in case 1 when the serum calcium was restored to normal by dihydrotachysterol therapy; they are therefore not to be confused with the nail changes which are part of a generalized ectodermal disorder that accompanies certain cases of hypoparathyroidism and are relieved by specific therapy. Furthermore, the fact that the changes were confined to the fingernails and did not involve the toenails suggests an infectious as opposed to a metabolic etiology. With the Ellsworth-Howard test it was demonstrated that case 1 reacted normally to parathyroid injection; this rules out "pseudohypoparathyroidism." Attention is called to the previously reported association of papilledema and increased intracranial pressure with hypoparathyroidism; their combination in case 1 with jacksonian epilepsy led to the faulty diagnosis of brain tumor. The authors also point out that other observers have reported the histories of 2 siblings in both of whom moniliasis was associated with Addison's disease and in 1 of whom hypoparathyroidism was also present.

Infantile Toxoplasmic Encephalitis.—The following characteristics are presented by toxoplasmic encephalitis in infants, according to Steiner and Kaump: The onset of symptoms is at birth or during the first weeks of infancy; convulsions and possibly other organic neurologic manifestations, internal hydrocephalus, chorioretinitis and cerebral calcifications are present which can be demonstrated by x-ray studies. The cerebrospinal fluid yields a high protein content, an increased cell count and

occasional xanthochromia. Pathologically the disease is characterized by focal meningeal and cerebral inflammatory lesions, necrotic areas showing advanced calcification, miliary granulomas and the presence of the causative organism either singly or multiple in cysts. The toxoplasma is a parasite classified as a protozoan. The mode of transmission and the port of entry into the human body are not known. Pregnant women seem to transmit the disease to their offspring before birth without themselves acquiring clinical manifestations. The authors present a case of infantile toxoplasmic encephalitis. It was complicated by erythroblastosis fetalis. Toxoplasmic encephalitis in its severe form is essentially a disease of early infancy and appears to be acquired in late prenatal life. The immature brain of late prenatal and early postnatal life appears to be susceptible to toxoplasmic infection; the infantile meninges and brain appear to have a low resistance to toxoplasmas. The fully developed toxoplasmic cyst produces no reaction and no granuloma. When the cyst ruptures there is at first likewise no reaction. However, as the parasites begin to spread, formation of a granuloma begins. The final reaction to the free toxoplasmas is the fully developed granulomatous lesion. The diagnostic criteria in infantile toxoplasmic encephalitis include gross and microscopic pathologic changes, morphologic identification of the organism, the clinical picture, the isolation of the organism and the presence of immune bodies in the blood of the mother and the infant. The history and the gross and microscopic aspects of calcification, necrosis, inflammation, parasitic cysts and single parasites are of greatest importance in establishing a diagnosis.

Subdural Hematoma in Infancy.—Ingraham and Matson present observations on 98 children with subdural hematoma, all of whom were treated under supervision of the neurosurgical service according to a uniform plan. This group includes only patients seen since 1937. Previous to 1937 only 2 or 3 patients a year with subdural hematoma were seen. The authors feel that the apparent rise in the incidence of the disease in their hospital population during the last six years is not a real one. Increased interest has led to a more diligent search for these patients, and the results have been gratifying. The authors stress that subdural hematoma is most frequently seen in the first six months of life. Trauma to the head is probably always a factor. There is no characteristic clinical picture. Generalized symptoms such as fever, vomiting, hyperirritability and failure to gain in weight are frequently found alone or in addition to the more specific neurologic findings of convulsions, stupor and paralysis. Infants who show early abnormal enlargement of the head should never be abandoned as having incurable hydrocephalus until subdural hematoma has been ruled out. The diagnosis can be made by bilateral puncture of the subdural space, the technic of which is described. The increase in brain volume during the first two years of life must be unrestricted to insure the normal mental development of a child. Therefore radical craniotomy with excision or wide decompression of constricting subdural membranes is essential if cerebral deficiency is to be avoided. Infants during the first two years of life will tolerate radical surgery well if proper preliminary measures and supportive treatment are undertaken. The therapy used at the Children's Hospital since 1937 is discussed. In all of the 98 children treated by the authors the diagnosis was made on the basis of subdural puncture. In 94 of these, bilateral

temporal burr holes were made. Sixty-two patients showed subdural membranes on one or both sides. Ninety-four craniotomies were performed, with an operative mortality of 5.3 per cent and a case mortality of 7.9 per cent. Of the 57 patients who have been adequately followed for periods of from 6 months up to 5 years of age, 23 per cent are retarded or grossly deficient and 77 per cent show normal behavior for their age. These results, it is felt, have sufficiently improved the outlook in subdural hematoma to call for a more diligent search for these infants. Whereas treatment is fundamentally a neurosurgical problem, suspicion of the diagnosis must rest primarily with the pediatrician and the general practitioner.

Treatment of Diarrheas and Dysenteries in Young Children.—Glaser and Bruce review observations on infants and children with epidemic diarrhea or dysentery who were treated in the Louisville General Hospital during July, August and September from 1938 to 1942, with special attention to the patients of 1942. They divide their patients into two groups, those with diarrhea and those with dysenteries. In the first group they placed all cases classified as nutritional diarrhea and those which were caused by parenteral infection. The second group contains all cases of "specific" diarrhea caused by organisms belonging to the dysentery group. Except for the isolation technic observed in dysentery and the different selection of sulfonamides, the authors have applied the same method of treatment in the two conditions. Rest is essential and was provided. During a period of starvation lasting twelve hours only water and medication were given. The prevention or treatment of dehydration is of greatest importance. By cup or bottle, water was offered at fifteen to thirty minute intervals. In cases of advanced dehydration or acidosis, fluid was given not only orally but also intravenously. By continuous drip through a fixed ankle vein cannula, a steady flow of isotonic solution of sodium chloride, 5 per cent dextrose in sterile water or one of the two Hartmann's solutions was given for the first thirty-six hours. After hydration has improved, blood transfusions are of value. When hemoconcentration is too high, plasma has been given. The nonspecific type of diarrhea was treated with sulfathiazole and the specific diarrhea with sulfaguanidine. Because of delayed diagnosis, however, some specific types were treated with sulfathiazole. Bismuth compounds and camphorated tincture of opium were used only in resistant cases. In 1 instance polyvalent dysentery antiserum was used with striking result. Beginning twelve hours after admission the infants are given as much milk as they will take. The amount is neither limited nor forced. The orders read "Buttermilk as tolerated," or "Skimmed boiled milk ad libitum." The authors found this method successful. It has decreased not only the length of hospitalization but also the death rate.

Detoxication of Neoarsphenamine by Various Organic Acids.—McChesney and his collaborators made further studies on the detoxifying action of several organic acids, particularly ascorbic acid, on neoarsphenamine. They found that the toxicity of neoarsphenamine for albino rats is materially reduced by

ascorbic, isoascorbic, d-glucoscorbic and p-aminobenzoic acids. The most favorable effect is obtained if the arsenical and protective agent are injected intravenously in the same solution, but the acids are somewhat effective if injected simultaneously at another site. The function of the ascorbic acids appears to be primarily that of preventing oxidation, chiefly after injection. The mechanism by which p-aminobenzoic acid reduces toxicity is obviously different. There is evidence that the therapeutic efficiency of some typical arsenicals is not altered by the detoxicants.

Renal Cysts.—According to Braasch and Hendrick, renal cysts are formed by retention of renal secretion consequent to obstruction in the renal tubules. They assume clinical significance only when they become so large or so numerous as to cause renal dysfunction or when they become apparent on physical or urographic examination. The authors limit this discussion largely to the clinical data involving the so-called simple cyst. They show that the term solitary cyst applied to a renal cyst is a misnomer. Examination at operation or at necropsy usually reveals other small cysts in one or both kidneys. Urography, either excretory or retrograde, offers the simplest form of diagnosis. The excretory urogram will offer sufficient diagnostic data in many cases, but greater accuracy usually is obtained by the retrograde urogram. The differentiation of urographic deformity caused by renal cyst from that caused by renal neoplasm may be exceedingly difficult and is a frequent cause of diagnostic error. In most cases surgical exploration will be advisable in order to establish an accurate diagnosis. Multiple simple cysts may be confused on surgical exploration with polycystic disease. Multilocular cysts differ from the ordinary type of multiple simple cyst in that a single large cyst is subdivided into smaller segments. Peripelvic (pyelogenic) cysts are differentiated from simple renal cysts in causation, clinical course and treatment. Cystic hypernephroma occasionally may be confused with simple cyst, both on clinical and on casual surgical examination. Hypertension seldom is caused by simple cysts. The frequent incidence of hypertension in cases of polycystic disease is in contrast. Aspiration of cysts as a diagnostic procedure occasionally may be indicated in cases in which surgical exploration is inadvisable. The procedure, however, may be unsatisfactory because of possible error of diagnosis and complications which may follow it. Surgical exploration usually is more satisfactory than aspiration, and surgical excision of the cyst is a better treatment.

Carcinoma of Spermatic Cord and Epididymis Extension from Carcinoma of Stomach.—Lewis and his associates present the history of a 19 year old private in whom a swelling in the right scrotum was the presenting symptom. The diag-

nosis was at first obscure, as the early appearance of the scrotal mass overshadowed the relatively minimal gastrointestinal symptoms. Removal of the scrotal mass disclosed an anaplastic carcinoma. The patient died about six weeks later, and necropsy disclosed primary carcinoma of the stomach with extension by direct peritoneal implant down both inguinal canals involving the cords on both sides and the epididymis on the right side. The family history revealed that the father and a paternal uncle both had died of cancer at an early age. This stresses the importance of familial tendency in cancer. This is only the fourth report of the extension of an intra-abdominal tumor to the spermatic cord and epididymis. This case emphasizes to the urologist the importance of looking further afield in obscure cases of testicular disease.

*Rapid Detection of Sugar in Urine: Using a Modified Bismuth Oxychloride Spot Test. F. P. Guidotti and J. H. Winer.—p. 111.

Rapid Detection of Sugar in Urine.—Guidotti and Winer point out that Matticé suggested the dry hygroscopic bismuth oxychloride powder mixture (galatest), having used it successfully for screening out the "negatives" in a diabetic clinic. To determine the accuracy of this test, comparative series of 15,000 urine specimens were studied using the bismuth powder and Benedict's test simultaneously. The powder test proved valuable. Small heaps of dry powder are placed in rows on white paper and are pressed down lightly with the bottom of the vial. One small drop of urine is deposited on the powder. When positive, the white powder turns gray or black instantly. In the comparative tests the urine was simultaneously added to the preheated Benedict's solution. The powder does not give a satisfactory quantitative estimation; therefore Benedict's test is necessary for rechecks, which are performed when sugar is found. The authors conclude that the accuracy, reliability and speed of mass urinalysis are enhanced by the use of a dry bismuth oxychloride mixture for spot test examination for sugar.

Eruptive Fever Involving Mouth and Eyes.—Murphy reports that a man aged 22 was hospitalized three days after he had noticed a swelling between the upper lip and the gum. Later blisters began to appear on the buccal mucous membrane. At the time of hospitalization he had a temperature of 101 F. The conjunctivas were diffusely inflamed. The buccal mucous membrane, gums, palate and uvula were covered with many tight

vesicles. There was also a small amount of red inflammatory reaction and sticky exudate about the urethral meatus. During the first two days of hospitalization the disease ran an alarming, fulminating course. The temperature rose rapidly and ran a hectic course, up to 104.6 F. All the pearl-like vesicles in the mouth ruptured, leaving a loose, dirty, whitish slough. By the third day there was a massive slough involving the entire mucous membrane of the mouth and sparing only the tongue. The nasal mucous membrane sloughed in a less dramatic manner. Large blebs appeared on the glans penis also with superficial sloughs. Both conjunctivas were inflamed, but no vesicles formed about the eyes. A semipurulent exudate flowed continually from the eyes. On the arms and legs punctate red areas appeared and expanded, and in the center of each a vesicle appeared. These vesicles ripened into thin walled bullas and ruptured. On the fifth day the temperature fell and the patient began to improve. The sloughs in the mouth and on the penis were not complete before the third week. A conjunctival culture yielded *Staphylococcus aureus*. Smears of the bullas were negative both for eosinophilic polymorphonuclear leukocytes and for organisms. No significant evidence of the heavy metals was found on qualitative tests of two twenty-four hour urine specimens. The patient had had a mercury-amalgam tooth filling one and one-half months previously, but no other significant metal or drug history could be elicited. The therapeutic measures included sulfadiazine for five days, the forcing of fluids, colonic irrigations, calcium gluconate intravenously and salves, washes and other local applications to the mouth, penis and eyes. At the end of seventeen days the skin lesions had crusted and mostly fallen away. The author says that nothing is known of the fundamental nature of the disease or of its etiology. Neither drugs nor Vincent's organisms have been implicated. The disease is not typical of erythema multiforme, and it is the enanthem rather than the exanthem that is its constant feature.
